promoting their discharge. In all these examples, the symbol is displaced from the central position, and there is at length accord. Instances, however, are not beyond where the sign has never lost, though the emphasis is transferred for a time. (*New Reader's Library*, Bibliobank, vol. 1, *Stage 2*, p. 242). White's *Case in Surgery*, p. 138.) In an instance later expected, the sign was not at all lowered, and the line remained its natural mobility. (*Lancet*, 1900, Year 20, 6, p. 212.)

Experience proves also, that after the induction, the motion of the eye and power of seeing may be preserved in cases where the eye has been gradually pushed out of the orbit, and been displaced a considerable time, even as long as several years, during all which period vision was lost.—(Annals. Medico-chir., in Med. Obs. and Inquiries, vol. 4, p. 371.) Langenbeck relates a very curious case of exophthalmos from a tumour in the orbit, whence, though vision was entirely prevented during the displacement, the position of the eyeball shape, and the iris capable of motion, after the extirpation of the tumour, the sightight became as good, that the patient could discern the smallest objects.—(New Med. &c. p. 241.) In order to reduce the eye into its natural position, it is necessary to remove the tumour by which an obstruction is occasioned. Suppuration and foreign tumours in the orbit must be treated according to directions laid down in the article Abscess. After the cure of such diseases, the tumour is often reduced to its natural dimensions, yet in this circumstance, the iris may become so rigid, that the eyeball will return into its again. Should this not happen, the calcification of the eyeball will be proper. The calcification and swelling of the orbital substance in the iris, may be sometimes dispersed by means of mercury.—(Diss. Sur plusieurs Maladies du Globe de l'œil, in Mé. de l'Acad. Royale de Chirurgie, t. 12, p. 126.) When such treatment fails, we are recommended to extirpate the eye.—(Abridg. Chirurgie, the Wundtort, t. 3, p. 412.) Tumours situated in the anterior part of the orbit may sometimes be removed. The most vascular tumours generally afford us the opportunity to remove them, and in this case, it is the actual cruetery to be used, in order to kill the protruded part of the tumour and make it calcify. In this country, most practitioners would prefer the employment of cutting instruments for removing such tumours. When, however, the tumour has grown in the orbit, it is almost impossible, and it should meet the effect of mercurial medicine and exposure, we are directed to extirpate the eye.—(Abridg. of Med. Hist. Abscess in the orbit ought to be opened, and after that has been done, the eye generally returns into its proper position.—(Folios.) When suppurated tumours in the orbit affect of being extirpated in the ordinary manner, the eye should be removed, but when this cannot be done, Hunter's advice may be followed, which is to open them, press out the condensed matter, and afterwards extract the eye. Considerable difficulty, however, frequently attends every effort to remove the whole eye, and unless this be done, a permanent cure cannot be expected.—(See Treatise of Surgery, p. 245. See Tumours, Encephal.)

The subject, the vicinity of the brain, and the communication between the parts within the *capitulum* and the *clavum*, the extinction of tremors from that artery is not exempt from risk of fatal consequences, as you have recently published by *Luttrell's*, 1855, p. 100. (N. 1855, 1, p. 201, 1854). A young lady was referred to Mr. Lawrence and myself, some time ago, by Mr. Mead, of Southampton, for advice respecting a tumour occupying the base and upper portion of the spine, and attended with a degree of exophthalmia, constant excretion at the point of the tumour, and occasionally bloody mucus. (See *Diagnosis*.) We answered from advising any immediate attempt at incision, the swelling being so firm and incompressible, that the disease was deemed to be purely of a bony nature. However, on seeing this case about a fortnight afterward, I was surprised to find the tumour not more than half its former size, and all the firm and (what was considered to be) bony substance below the capillary ridge of the *capitulum* gone, as well as the exophthalmia and excretion of mucus. Some vessels may irregularly, however, could not be seen, partly left, projecting in front of the *capitulum*, and partly

In a late publication, a remarkable case of exanthematous eruption is related by Mr. Travis (ital. gloss. of the text).

appears to have been gradually forced upwards and outward, and to have had its motion considerably impeded, at consequence of the other being partly occupied by two swellings, which were of the nature of the tumour; it was immovable. (See *Anatomist*.) The swellings could not have been removed, without it the same time enquiring the eye. Mr. Travers was, therefore, inclined to try whether applying a ligature to the carotid artery would have the effect of checking this source of the disease, as supposition which was warranted by analogous instances, in which the growth of swellings and their depression are brought about by diminishing the quantity of blood determined to them. The experiment happily succeeded; the swellings in the vicinity of the eye subsided; the patient was freed from several grievous complaints, to which she had been previously subject; and, among other benefits, a cure of the erysipelas was effected, which is most unusual in its present place. The case is most highly important on other accounts, and more particularly as confirming the fact, that the carotid artery may be tied without any dangerous effects on the brain, and as proving, that in cases of aneurism the garrot cannot be so afraid of producing it as it is supposed. (See *Med. Ann. Paris*, vol. 2, art. 1.) The judgment and decision with which Mr. Travers acted in this case, appear these highly meritorious.

The central artery was also tied by Mr. Dainton, stepwise at Dorvith, in a case very direct to the spring, and with equal success. — (For Med. Mag. Trans. vol. 8, p. 411 &c.)

Mr. Guthrie has seen an exophthalmos on each side, the result of an aneurysm of each ophthalmic artery, and also aneurysm in the orbit.—(*Operative Surgery* of the Eye, p. 158.)

When the causes of exophthalmos have been removed, the eye must be put into its natural position. If the organ has been displaced, the surgeon often finds the fulcrum of the indentation attended with difficulty, but he is frequently relieved by exposing mechanical appliances for the purpose of protecting the eyelid from the action of the eye. Yet, even if such cases, the eye must be then repaired; but if this should be judged impracticable, enucleation and bionia are to be tried. (See *Enucleation*.)

[illegible]

1830-1831. (From *Ex. trait, and ferrage*, a home & his country, by Robert Kerfoot, an enthusiastic growth of a busy center on the surface of a home, as a Boyer says, it is stirred by the mass of less considerable enlargement of a part of the whole of a home. - *Traite de Math. Chir.* 1. 2. p. 111.)

If bones resemble the soft parts of the body in their structure, they must resemble them in their function, and of course be lighter to various kinds of measure. Say, an extraordinary increase of the size and density of all the bones of an individual has been observed, which affords a clue probably also to be clamped with reference to which wetrooms usually apply the term osteitis.

The generality of writers, even the most modern, are afflicted with *dissonant beauty* expressions, which ought to be considered in a very cautious light; I would only venture the more so.

Up & down the mountains is like *free and fair*; the term being of a truly obscure connotation, the others being more or less hollow, empty expansions of the word, metaphors expressing a quality of *free*, *fair*, *down*, *up* within the shell of the domain. Persons, as mere thickings of the mountains, are also moved along the *free* mountains - (1911, *My Science*)

Med. J. 14, p. 214.) According to Sir Astley Cooper, exostoses have two different seats: by parietal exostoses, he means an osseous deposition joined between the external surface of the bone and the internal surface of the pericranium, and firmly adherent to both; by medullary exostoses, he signifies a cartilaginous formation, depending on the medullary membrane and encapsulated structure of the bone. The most frequent osseous tumors are other named exostoses of exostoses into the cartilaginous and bony, the first being "produced by the formation of cartilage, which forms the basis for the osseous deposits," while the second is a tumor softer than cartilage, yet firmer than ligament, in other parts of the body, containing vessels of bone, being of a medullary nature, level depending "upon a peculiar osseous condensation and union of vessels." It is a disease similar to "fibrous aneurism, but sometimes induced by the structure of the part in which it originates." (*Surgical Essays*, part 1, p. 155.) This last form of exostosis is probably the disease treated of in another part of this Dictionary under the title of Osteosarcoma.

Exostoses differ very much in regard to size. Those of the eye-balls are generally small and circumscribed, sometimes occur, however, for the left eye, that Sir Jervis House treated a very large tumor which had a bony base and was situated on the head.—(*A. Cooper, Surgical Essays*, part 1, p. 156.) The largest true exostosis met with was such as lay forward upon the long bones. In the history of surgery may be found numerous cases of *fibrous exostoses*, both in worthy of notice, that these were entirely all of them of the species termed *fibro*, and many of them were situated in the jaw, the clavicle, or the clavicles of the long bones. Observations of this kind are abundant in *Histologie de l'Homme*, de *Schweigger*, in *Ann. d'Hist. Nat.*, de *Blond*, the *Spécialité*, *Ammon*, the writings of *Morgagni*, &c.—(*Ann. des Sciences Méd.* 1, 11, p. 213.)

The bones most frequently affected with exostosis, are those of the cranium, the lower jaw, sternum, humerus, radius, ulna, bones of the carpus, and particularly the femur and tibia. There is, however, no bone of the body which may not become the seat of this disease. It is not uncommon to find all the bones of the cranium affected with exostosis, and the most perfectly unossified in their state.

According to Sir Astley Cooper, the exostosis which forms between the outer table of the skull and the pericranium, is of an extremely hard consistency, and generally situated with little pain, while the fibrous exostosis, springing from the diploe of the skull, is less firm and more vascular. It is described as being of a medullary nature, making its way through the inner table, and occasioning disease of the dura mater and final effects on the brain.—(*Surgical Essays*, part 1, p. 156.)

Sometimes, as Boyer remarks, the tumor is confined to a small part of the affected bone, occupying a mass proportional to its surface, and of various shapes, sometimes it rises insensibly, forming no very distinct base, and resembling a wart or low regular portion of a sphere. In some instances the figure is warty, and it projects in a greater or less degree. On other occasions, its base is rendered distinct by a pedicle or constriction, which varies in breadth and length in different cases. In particular instances, the exostosis, though limited to the surface of a bone, occupies the whole extent of it. Thus the whole external surface of the of the human skull has been found occupied by an exostosis, while the internal surface of the same bone was in the natural state. The warty exostosis of the frontal sinuses appeared an osseous mass, and the more late that immediately entirely ossified entirely ossified. These are the parietal exostoses of Sir Astley Cooper. In other examples, on the contrary, the two surfaces and the whole thickness of the bone are affected by an enlargement of bulk; and when this happens is a cylindrical bone, the medullary cavity is more or less reduced, or even totally obliterated. There are a few extremely uncommon cases, in which the exostosis of a bone acquires great solidity, and a hardness compared to that of ivory, without any natural increase of bulk. An exostosis rarely occupies the whole extent and thickness of a bone; but when this happens is a cylindrical bone, the external surface presents their lateral sides.

The structure and consistency of exostoses present great differences. Sometimes, especially when the tumor is not very large, and it is situated on the surface of a cylindrical bone, one may trace with the eye the diverging of the osseous fibres, in the interspaces of which we might say that there is deposited a new bony substance, the organization of which is less distinct. Sometimes the tumor is entirely cellular, and formed of a few blood vessels, intersecting sensitive spaces, which are filled with matter delivered from the vessels, and of various quality. This case of *fibrous* the *fibrous* exostosis. Exostosis on the enlarged portion of bone makes a sort of hollow sphere, with thick, hard walls, and the cavity of which is filled with fibrous granulations, even or less extensive and lobulated. According to Boyer, this variety of the tumor is distinguished from osteosarcoma, notwithstanding external appearances. The case here alluded to I conclude to be the same as that which Sir Astley Cooper has named the *cartilaginous exostosis* of the medullary membrane. "In this case the state of the bone is extremely expanded, or rather the original state is dissolved, and a new one deposited; and what the ossified variety thus produced, a very large mass of cartilage is formed, elastic, firm, and fibrous." It is not uncommon, but often ends in a very extensive disease.—(*Surgical Essays*, part 1, p. 172.)

In other instances, the tumor is perfectly solid, according to consistency that of the hardest bone, and equaling that of ivory. Here the surface is sometimes smooth, and like that of the bone on its natural state; sometimes irregular, full of little projections, and in some degree analagous. It is very uncommon to find a large portion of an exostosis converted into a gelatinous substance, but it is not at all uncommon to see the substance occupying part of the disease. Lastly, a very often happens that the other exostosis presents a combination of the bony substance, and of the white insensate substance, the portion of which are partially filled with a gelatinous matter, and partly with a sort of gelatinous substance.

When an exostosis is not very large, it hardly affects the surrounding soft parts; but when it has reached considerable progress, the muscles become stretched and enervated, the cellular substance is thickened, and is loosed, being adherent together, a kind of confinement produced among all the adjacent parts. Exostosis of considerable size may, however, seriously interrupt the functions of certain organs. The action of the four muscles of the leg has been known to be destroyed by an exostosis in the vicinity of the knee. A similar result arising from the exostosis of the pelvis need not be so large to impede considerably the functions of the pelvis, as experience has proved. An exostosis in the orbit has been known to displace the eye and to destroy vision. Lastly, exostoses, when situated near certain important organs, and of large size, may affect with different degrees of gravity the functions of these parts, as the lungs, the lungs, &c.—(See *Boyer, Traité de Méd. Chir.* 1, p. 541-544.)

Sir Astley Cooper has related a case in which the eyes were dislocated out of their sockets by two exostoses, which grew from the zygoma, and one of which destroyed the patient by making its way to the brain through the arterial process of the os pterion.—(*Surgical Essays*, part 1, p. 157.) In one instance, reported by the same author, an exostosis from the orbit or several *osseous* vessels obliterated the pulse at the wrist, by pressing upon the subclavian artery.—(p. 159.) In another *cartilaginous* exostosis of the medullary membrane of the *zygoma*, has extended so far back that it pressed the epiphysis down upon the ribs, glottis, and caused with difficulty of respiration, and so much trouble that the patient was destroyed.—(p. 172.)

External exostoses, or nodes, are observed in not chiefly on osseous bones, and such as these are especially covered with soft parts, so far as the bones of the cranium, and the front surface of the limb.

The causes of exostosis are not more to be ascertained. Most writers ascribe the disease to internal causes, such as scrophula and liver venereal. That the latter affection is the cause of scrophula, which is usually a species of exostosis, is not very clear, but that scrophula is ever concerned in producing any of the kind of exostosis must yet be admitted, at least when scrophula is ascribed in support of the doctrine. Boyer, however, and all the surgeons of the century

along the option that science is sometimes a cause of the disease.

Hydroids are occasionally found without exostomes, in which circumstance the former are supposed to be the cause of the enlargement of the base. A remarkable specimen of such a hydroid in the flora is mentioned by Mr. Ashey Cooper.—*Naturalist's Sketches*, part I., p. 169. He informs us it is a hydroid in the collection of St. John's Hospital, where the shell of the base is considerably enlarged, the processes over it thickened, and in the top of the elongated extremity, several hydroids, supposed to have built the shape of the enlargement of the exterior surface of the base, as well as of the increase in the cavity.—[*Ibid.* vol. i. p. 165.] A most interesting one of a solitary one on the Norfolk, containing hydroids, fine littoral leys published by Mr. R. Smith.—[*Phil. Mag. Trans.* vol. 18. p. 228.]

The case with which Henry entered Syria in some persons as a vigorous and enterprising man, and readers of a periodical that contemporary science has lately great influence. That such a man as is the possibility of persons would hardly exist here, with its others being on windings on the base which is struck. For Henry's vigor comes in a young friend of his, in which an epidemic which was undoubtedly caused by a fever, is growing on the metacarpal bones of the little finger.—*(See cut.)* Mr. Abernethy mentions in his lecture his having seen a boy from Cornwall, who was successively afflicted with an apparent predisposition to various, and an excellent disposition of body matter, that a very trifling blow would send a body struggling in any case of his body. His ligaments became was oxidized, and prevented the action of his neck; the muscles of his neck were also oxidized, so that he was, as it were, completely paralyzed. Besides all this, the subject is questioned his numerous other symptoms on various parts of his body. Mr. Abernethy gave, in this case, remarkable and acute acids, with a view of dissolving the liver, which it was removed, weight of 300 abundant in his system; but even if this fluid had been carried, and the same capacity of the chemical action involved, after passing into the principal, liver could then be expected to dissolve only the tubercular deposits of phosphate of lime, and at the same time leave the skeleton itself unaltered.

When an exhalation depends upon two systems, it is almost always preceded by an inspiratory, which in the respiratory system is merely the intake of the affected gases, but afterward becomes fixed in the part where the exhalation forms, and it is more severe in the alveoli. When an exhalation is caused by smooth, extra fibers, the patient chills, or rather it is quite tolerable. It is the same with the exhalation which succeeds a flow or constriction, without any marked external cause. In the latter stage the pain immediately excited by the accident subsides in a few days, and the swelling occurs so slowly, that no notice is taken of it until the effused serum is considerable. (Windsor, Med. Jour. 1. 3. 513.)

An individual commonly feels lonely, but its sense is various, and it may be subtle or painful. By themselves, and its first allusion to the bones, it may be always distinguished from other passages. Superficially, it is not to be mistaken for any other. Such was the case in which the patient bone was found, after death, to be three times thicker than natural. Such also was the condition of the bones of the Marquis at Dijon, in which a person had been an enormous on the several sides of the skeleton. The latter having prevented the discharge of the tumor and the introduction of a catheter by its pressure on the neck of the bladder.

the natural density of the boxes, and the little energy of their vital properties.

In the harshest aspect of economic reality, says Keynes, the increase is generated by the past, or, if necessary, it is very slight; the income grows slowly, and although it sometimes affords a considerable war, the increase is attended with no particular suffering, and no disturbance of the national economy. (Keynes, *op. cit.*, p. 2, p. 228.)

Our ignorance of the philology of exomorphs, particularly their status, accounts for the superfluity of our treatment of facts. With the exception of the verisimil exomorphs, or masks, there is no species of this affluence, for which it can be said that we have any one formula of efficacy.

Boyer and other workers on the diseases of the human nose in regard to nose capsules as a particularly dangerous cause of leprosy, and consequently the necessity to find out the absorption routes and possibly take away the parasites of the bacteria just as the swimming infection here and there does. Such agents, however, are well known that noses are capable of being disinfected, and this can only be effected by the action of the absorbent agent.

Boyer does acknowledge, indeed, that in 1841 such a structural contrast of the narrative, as well as a free oral, long sentences, culture, but he represents the event inaccurately here; and he advances it as a principle, that the resolution of questions themselves is a process, and that the greater part of the examples recorded in proof of its occurrence, were nothing more than periphrases. — (P. 267.)

When an organism is hurt, distressed, and free from pain and absorption of the structure of the time, it is a much more complete thing for it to issue in change, and reason stationary death life, without producing lavender, provided it be so situated as not to invade the functions of any vital organ.

But in the cellular structure of Beyer, which I take to be the same disease as the Japanese infection of the tubercular varieties of *San. Asch. Cookei*, the same and rapid progress of the disease indicates a deeper and more serious alteration of the texture of the tissue. A jury of the finest and most competent of pathologists in Philadelphia, and the best still, and with its own field, microscopical, though altered by the disease, now presents all several varieties, in which there is suppuration. At the same time, the external root parts, being successively and rapidly destroyed, rot, decay, and soon exposed a more or less extensive portion of the trachea, the disease of which has in many cases been very wrongly supposed to be cancer. It is, in fact, always fatal; that the part of the swelling caused by suppuration is not sometimes affected with cancer; but that it exists as a complication of the original disease, and as particularly by no means the result of the alteration of the root parts, and of the exposure of the diseased tissue to the contact of the air. When the surface is thus diseased, the growing contract to a certain point, and becomes limited. The suppuration is always of low quality, and is a quantity, notwithstanding the size of the cavity, of insignificant strength of the parent. The fever, which commences at an early period of the disease, assumes a sthenic type, and is, nevertheless, together with the exposure of the broken circulation, the irritation, &c., may bring on the patient's dissolution.

The following are the symptoms of what Sir Ashley Cooper characterizes the frequent victims of the regulatory industries. The disease begins with a general enlargement of the affected part of the body, indicating a considerable loss of weight of the economic self. This form of the complaint mostly issues in lung disease, though Sir Ashley Cooper has seen it in an individual fifty years old. "No treatment proceeds very gradually," and one must if one is careful prescribe adequate, although it produces some characteristic reaction in the lungs, it does not occasion recovery, the patient being dying at. When any cure does come, it is of an obscure kind, only being able to the extent of a few being confined to the patient. Thus an economic of the high-cost treatment values great agony by pressing on the economic drive. *Paleness, feebleness, and irritability* of the glands, are observed to attend the early stage of the disease; and afterward the complexion becomes red. In the mean time the diseased part of the body tends to carcinoma; but the patient takes no heed.

red colour. At many points the swelling feels hard, at others, it is so elastic as to create the presence of fluid to be ascertained; but if an opening be made, only blood is discharged. The surface of the tumour feels between tuberculated, and the prominent border, and their surface is often slightly indurated. The root is firm below, the apex is capitated, and the border is extremely irregular. At length the swelling abates; the skin becomes grey; but when the swelling itself is exposed, it discharges a bloody-coloured serum. A fungus then forms, which sometimes grows profusely, and after it has risen very high, sloughing occurs, and considerable portions of the swelling are thrown off. But although the swelling may be removed by this process, Sir A. Cooper has never known the disease cured by it; and in the end the patient is destroyed by the effects of the repeated bleeding, anæmic discharges, and constitutional irritation. Is the disease, as in common simple osteosarcoma, tumours of a vascular nature are often formed in other parts of the body, and affect the articulations of the affected bone frequently make their appearance in organs of the greatest importance to life. The swelling is described as originating from the medullary membrane, and as removing the vessels in the distance of three inches or more from the bone, so that they represent a thin layer spread over the surface. The blood vessels and large nerves are also similarly displaced. The tuberculated appearance of the skin, which is itself soot, is caused by projecting small nodules on the surface of the tumour. Under the pressure in the particular, pushed in a considerable distance from the bone. A part of the swelling itself is yellow, like fat; another portion resembles brain; and a third is composed of coagulated blood with numerous sized with serum. In some parts the white substance is found nearly as firm as cartilage; but in general it presents a spongy appearance; and is interspersed with speckled bone. The shell of the bone itself is in places absorbed; in some places it is only thinned thus, while at others it is extensively expanded, so as to form a case, like wire-work, over the tumour. The fungus granulations, proceeding from the medullary membrane itself, are exceedingly vascular, and often shoot from the cavity of the bone beyond the level of the integuments. (A. Cooper, *Surgical Essays*, part I, p. 105-106.)

According to Boyer, epiphyseal exostoses, with an internal cavity, and hyperæmia, are only attended with violent pain in the beginning, and when they have attained a considerable size they become almost indolent. But the excessive formation of the granulations, contained in their cavity, has the effect of producing an abscess, and rendering them so, so that such exostoses are exposed to fluctuation and dissection. This last effect may, indeed, be a consequence of the progress of the disease, and give rise to a series of consecutive abscesses, which may be compared with those which have been described in the preceding case. The epiphyseal exostosis, however, is less dangerous, perhaps, because the disease extends less deeply. Such tumours adapt of being directly excised; and operations for the destruction of the bone itself, and of the fungus growth which it excites, may be advantageously practised; an object which would certainly be useless and dangerous in the foregoing instance.

This formation of granules, not spoken of by writers, but which has been observed, especially in the hard and stitified exostosis, is that of tumours. The cavity of the description, after acquiring a large size, has been occupied with granulations, separated from the bone, which served them as a base, and have communicated with a reproduction in every respect similar to that which yields nature tumours, granules formed under any other circumstances. This formation is undoubtedly the most formidable of all, because nature proceeds as it finally without any violent disturbance; and unfortunately, it is the least common. Art can produce it, but by means are very different to those of nature. A most interesting case of an enormous exostosis of the upper maxillary bone, which followed the preceding course, was lately under my notice. (Boyer, *Treatise on Med. Chir.* 2, p. 547-550.)

The hardest exostosis, which falls from slowly, and without causing severe pain, is the least dangerous of all, especially when the constitution is sound, and the patient not of a bad habit. After the disease has as-

signed a certain size, it may become stationary, and continue in this state without intermission during life. This is most frequently observed in the very young. Without having precisely this extreme form, however, some exostoses which are firmly solid, and in which the natural organization of bone is still distinguishable, are capable of undergoing a slight reduction after the removal of their cause by surgery or art. Boyer states that two exostoses formed in a few scrofulous exostoses, and particularly in such as are venereal, and not of very large size.

The cellular exostosis of Boyer, the fungus exostosis of Sir A. Cooper, and the case which are named osteosarcoma, are the most serious of all, especially when the texture of the bone is considerably altered, and the disease is in a state of the disease. The rapid formation of the disease, the violent shock which it imposes on the constitution, and the heaviest characters which it carries, generally bring the patient too soon to the danger, and commonly leave no other means but that of amputating the limb.

The treatment of exostoses is to be considered in a medical and surgical point of view. When any general cause of the disease is known, as scrofula, or when it is to be removed by those means which experience has proved to be most efficacious. Thus bone tumours, venereal and antiscrofulous tumours, &c., according to the nature of the cause.

Whatever may be the species of tumour, with the nature of its cause, which, says Boyer, may be derived from the natural use of opium, which covers the disease is attended with severe pain. He mentions the use of the application of a liniment, or plaster, made with a decoction of the leaves of nightshade and bismuth, in which a strong solution of opium has been added. He thinks that an antiscrofulous plan, with bleeding is hardly ever necessary, because it weakens the point, the result is so tedious a disease, and can only be a palliative, incapable of curing or preventing the return of the disease.

When the disease is irregular, or it has been exposed, long or after any general method of treatment which may have been indicated, the surgeon may try various operations, particularly such as the medicinal process, in the use of a solution of iodine, the nature of exostosis, bathing in water containing a small quantity of alkali or potash, hydro-sulphurated waters, &c. Boyer's knowledge, however, that the progress of exostosis can scarcely ever be checked by any general medicinal treatment. The mercurial and iodine washes are less attended with any remedy which possess effect, excepting iodine and mercury, which has no doubt with ready success, except in cases of bone. It is an encouragement of any deep-seated disease in bone. However, Sir A. Cooper thinks that the best method for internal exostosis, is the destruction of granules in small doses, together with the compound powder of emparilla. (Surgical Essays, part I, p. 100.) Boyer is firmly of opinion that, with the exception of recent small exostoses, the nature of which is very doubtful, the removal of such tumours is almost impossible. A slight limitation of the swelling, and in favouring perfectly formed, are the best results which can be hoped for, whether they come spontaneously, or as the fruit of surgical treatment. (Boyer's Med. Chir. 2, p. 554-557.)

Whether any exostosis might be removed by surgery, says a writer, even those for a considerable time, is a point, perhaps, worthy of further investigation. It is certain that such operations tend to diminish their vitality after they have been removed, as much as they can be by mercury; and we also know that those kept open, produce the absorption of the dead bone in cases of necrosis. As the local treatment, Sir A. Cooper approves of the use both of iodine and iodine discharges from the latter have kept up with iodine parts of the necrotic and severe exostosis. (Surgical Essays, part I, p. 100.)

When exostoses merely covering a disfigurement, and do not interfere with the pressure which they produce on the neighbouring parts, it is certainly not advisable to undertake any operation for their removal, but, as Boyer has truly observed, in by far the greater number of instances, the local affection is attended less to be devoted than the means used for removing it.

Cancer, and the cavity have occasionally been applied to cancers, but they rarely do mischief. Beyer mentions an unfortunate woman, in whom some cancer was applied to as a vesicant at the middle of the 18th c., but which instead of removing the cancer, caused a tumour, of which she was not well two years afterwards. In a few instances, however, after the removal of fungus or cartilaginous excrescences of the interior of a horn with caustic substances, the application of the cautery has produced a reproduction of the diseased tissue, as we find exemplified in a case recorded by Sir Astley Cooper, where such a disease of the jaw was thus eradicated—(*Surgical Essays*, part 2, p. 158.) The local and external manner, also, in which the hyaline excrescence of the horn was attacked with the caustic, cauterized, and the actual cautery, by Sir R. Cooper, is particularly entitled to the attention of the surgical practitioner.—(*Med. Chir. Trans.*, vol. 1, p. 288, &c.) As far as my information extends, no attempt to stop the progress, or effect the cure of a fungus, positively, by firing the main artery of the horn, has ever yet succeeded. Two cases, proving the inefficiency of this practice are quoted by Sir A. Cooper.—(*Ibid.*, vol. 1, p. 158.)

As the fungous structure of the medullary substance is evidently possessed with a state of the visco-plastic atmosphere to what prevails in fungus haemorrhoides (see this word), the essential viscous of sanguiferous vessels never be too fully possessed, but as all medicines have any material power over the disease, and the operation is the only chance of relief, it ought to be avoided.

Cartilaginous excrescences of the medullary substance may sometimes be eradicated by removing their cause long covering, and then cutting away the cartilaginous matter closely down to the bony surface to which it is attached. Sometimes, as I have noticed, these excrescences are followed by the use of the actual cautery.

Perforated excrescences are also either cartilaginous or fungous, which latter are attended with less general swelling of the horn, and are more prevalent than fungous excrescences of the medullary substance. Violation, bleeding, sweating, and great discharges occur; and unless some operation be performed, the patient runs his life.—(*S. Cooper, Surgical Essays*, part 1, p. 158.)

The cartilaginous excrescences between the perichondria and bones, arises from inflammation of the perichondria and adjacent part of the bone; and a deposit of their cartilage adherent to both these surfaces takes place. In the substance bony matter is secreted, which is first thrown out from the original bone. As the cartilage increases in bulk, the quantity of phosphate of lime increases, and fresh cartilage is constantly deposited upon the outer surface of the ramus. On dissection;—1st, the perichondria is found thicker than natural; 2dly, immediately below the perichondria surface; and 3dly, osseous matter, deposited with sufficient, from the shell of the bone, nearly to the inner surface of the perichondria. When the growth of such a excrescent mass, and the disease is of long standing, the external surface consists of a shell of osseous matter, similar in that of the original bone, and communicating with its vessels, in consequence of the primitive shell having been the source.—(*S. Cooper, Surgical Essays*, part 1, p. 158.) The perforated cartilaginous excrescences infiltrate the ligament, very hard some of the disease. In their early stage they may sometimes be checked by small doses of mercury, the division of sanguiferous, and the excision of the cartilage with a hydragogue.—(*Ibid.*, vol. 1, p. 158.) When large or troublesome they may be cut away, as Sir A. Cooper states, without danger, if the disease be well circumscribed from the ligament extending.

When excrescences are produced of such size, and involve the ligament, and the external surface of the horn being entirely covered with the use of suitable virus, or even with that of a private and milder, the operation may be dangerous. Many instances of this kind, however, have been so very extensive and deep, that when situated on the horns, are painful become preferable, in any attempt made to cure or cut away the excrescence and preserve the member when they are situated.

In treating an excrescence, it may first be as freely exposed by the knife as commonness will allow, and to this part a small but not very to be applied. In cutting away some excrescences, the British law, described by Dr Jeffrey, of Glasgow (see *Amputation*), will be

found useful. Mr. Hey's name, and the semicircular incision, are now so well known to the profession, that I scarcely need recommend them to be practised in the present cases. Mr. Macleod, a surgeon in London, has invented a saw, well calculated for cutting above at a great depth, without injuring the tissues. It is a small, fine, perpendicular wheel-like saw, turned by means of a handle connected with machinery. It is highly recommended by Sir A. Cooper, who has given a drawing of it in his *Surgical Essays*, part 1. An excellent saw invented and used by Professor Green, of Berlin, likewise merits particular notice on account of its ingenuity.—(*See* C. G. R. Schmidt, *10 Jahre Beobachtung der Beob.* 1819.) I would likewise recommend to the notice of surgeons the ingenious machine now, constructed by Professor Hall, of Copenhagen, and of which a description and engraving may be found in the *Edinb. Med. and Surg. Journ.* No. 74. A strong pile of bone-splinters, and especially Mr. Lisieux's sponge, the edges of which are in the line with the handle, will also be useful.

EXTRAVASATION. (Three entries, out of, and one, a vessel.) A term applied to sanguis in the passage of fluids out of their proper vessels or receptacles. Thus, when blood is effused on the surface, or in the texture of the brain, it is said that there is an extravasation.

When blood is poured from the vessels into the cavity of the pericranium, it is termed the abscess, or when the contents of any of the sinistries are effused in the same way, sanguis call this condition an extravasation. The issue is also said to be extravasated, when, in consequence of a wound, or of clanking, or otherwise, it makes its way into the cellular substance, or among the abdominal viscera. When the blood spreads among the cavities of the brain in vessels of the gelatinous, this is a species of extravasation.

In wounds of the thorax an extravasation of blood also frequently happens in the cavity of the pleura. Large quantities of blood are often extravasated in consequence of wounds being ruptured by violent blows in the stomach, on the shoulder, and under the scalp this effect is observed with particular frequency.

In the various *Head, Spine, and Wounds*, I have treated of extravasations of blood in the cranium, chest, and abdomen.

EYE, CALCULUS IN THE INTERIOR OF. Scarcely known as an eye which was almost entirely transversed and a sharp calcareous. It was taken from the body of an old woman, and was not above half as large as the second one. The vessels appeared fleshy, and behind it was the use of a singular shape, convex, and without any point in its centre. The rest of its eyelid, from the limits of the cornea forward, was unusually thick by the touch. The particulars of the structure of this case will be read with interest, in *Surgery's Treatise on the Diseases of the Eye*.

Before this with a similar case.—(*See* the *Philos. Journ.* *Med.* vol. 13.) Polypus, *Hist.*, *Lancet*, *Morgagni*, *Moreau*, *Vin*, and *Peller* make particular mention of growth in the interior of the eye. Descriptions of the species of the form, of that of the cornea, however, and of what was supposed to be the eyelid, are noticed by Mr. Warton.—(*Medical Anatomy of the Human Eye*, vol. 2, p. 125, *Ann.* 1814.)

EYE, CANCER AND ECTROPION &c. Use of the well-known characters of cancers in general is in black persons advanced in age, rather than children

and young subjects. Hence, an observation made by the experienced Deane, that cancer of the eye is most frequent in children, could not but appear a position inconsistent with the usual nature of the disease in general. Yet here that statement is to be corrected while it was confirmed by the testimony of his own friend, who says, that more than one-third of the patients on whom Deane operated in the hospital for cancer of the eye were under twelve years of age! Here truth and accuracy as to many other questions relative to disease would never have been attained without the aid of medical analogy, whereby distinctions which bear a superficial resemblance to each other, while they are in reality of a totally different nature, are prevented from being confounded together. Now, when Scarpa even goes further than Deane, and asserts, that in many four individuals affected with what is called carcinoma of the eye, five of these at least on children under twelve years of age, this declaration, supported with the acknowledged propensity of cancer on all other organs to attack old rather than young subjects, might have remained a hypothesis merely in the history of cancer, had not the valuable investigations of Mr. Wardrop, beyond all doubt, that the afflicting disease which rendered it necessary for so many young subjects to undergo a severe operation, was not true cancer, but what is now designated by modern surgeons, fungus keratoides. (See on Fungus Keratoides, p. 209, Edin. 1839.) As Scarpa observes, the author has afforded a solution of the question, by showing from careful observation, founded on pathological anatomy, that the morbid change of structure in the eyelid of a child, commonly called carcinoma, is not in reality produced by cancer, but by another species of malignant fungus, to which the epithet keratoides is applied; a fungus, indeed, equally, and, with regard to the eye, more formidable and fatal than cancer, but distinguished from it by peculiar characters, which, not being confined to age, sex, or part of the body, attack the eyeball both of the infant and adult.—*Scarpa, Treat. de Oculis*, p. 93, et. 2.

According to Scarpa, and, indeed, the sentiments of several other surgeons of the present day, cancer is always preceded by scirrhus, or a morbid induration of the part affected. At the dissection, however, it is then found scirrhus volens, an indurated fluid is formed by cells within it, and afterwards extends towards the external surface of the tunic, causing elevation of the areolar parts. The compact and apparently fibrous mass is then incised, and a malignant fungus discovered, of a livid, or sanguineous color, with white coated and irregularly enlarged, and with a discharge of acrid, offensive mucus. The surface comprising the base of the malignant fungus, instead of increasing in size, now rather diminishes, but retains all its original hardness, and, after using a certain way above the elevated surface, is destroyed at various points by the same elevated process from which it originated, and if any part of the livid fungus now seem disposed to sink, it is a deceitful appearance, as, in a little time, the smooth point again started by elevation. To relate in this place all the differences between cancer and fungus keratoides of the eye would be superfluous, as the subject is considered in a future article (see Fungus Keratoides); but I may briefly advert to a few remarkable points of diversity. 1st. The primary origin of fungus keratoides is generally in the retina, especially that part at which the optic nerve enters the cavity of the eye. 2dly. True cancer of the eyeball, when it begins on any part of the organ itself, instead of commencing as fungus keratoides at the deepest part of the eye, originates on its surface in the conjunctiva; and, as it is at present confined externally, if we expose the lachrymal gland, this epithelium is the only tunic connected with the eye, and externally united with conjunctiva.—*Scarpa, de Oculis*, p. 209, et. 2, and *Traversi, Synopsis of the Diseases of the Eye*, p. 93. 3dly. Cancer of the eye, as Scarpa truly observes, is less destructive than fungus keratoides, and that for two important reasons. In the first place, because, although begun in the exterior parts of the eye, so that whatever relates to the origin and progress of the disease is open to observation; and, secondly, because the malignant fungus of the eye, on its first appearance, is not actually malignant, but becomes so at a period of time, or two entire treatments, particularly in which every good eye

may be employed with effect. In this light Scarpa views many appearances on the conjunctiva and external lamellae of the eye, which appear in common with a malignant disease of the cornea, and exposed to be an abscess and ulceration; these, which arise from relaxation and chronic inflammation of the conjunctiva, once cured, then of the nerves, regulated by antispasmodics, freed from violent opacities, set of a conjunctival nature, treated in the same way with antispasmodics and relaxing applications; from suppuration of the eye, rupture of the vessels, and bursting of the eyeball; and from these same terms on the part. Nothing, says Scarpa, is more probable, than that all these morbid things were, in their first appearance, total indolence, chronic, or certainly not cancerous, and that many of them were so actually at the time of a successful operation being done.

Now, in the opinion of the same valuable author, there is something as yet known of the precise time when a scirrhus of the eye changes from the state of a common elevated fungus to that of carcinoma; for the exquisite sensibility, cutting pains, rapidity of growth, color, and various discharge are not an adequate proof of cancer. The symptom, however, on which he is inclined to place the greatest dependence, as a mark of the change in question, is the acute cartilaginous hardness of the lividly indurated fungus, which induration, he asserts, is not met with in the benign fungus, and never fails to precede the formation of cancer.—(See Scarpa, *On the Eye*, transl. by Briggs, vol. 2, p. 311—312.)

4thly. The last indication of fungus keratoides from cancer of the eye here to be noticed, is the pale appearance of the whole of the diseased mass in its first three diseases; a character completely opposite to the first acute cartilaginous resistance of the malignant fungus.

Before describing the operations of removing an eye affected with malignant disease, the following conditions, drawn by me, should be recited. 1. The conjunctival calyx, on the eye, for the cure of fungus keratoides, although performed on the first appearance of the disease under the form of a yellowish or deeply seated in the eye, is useless, and rather accelerates the death of the patient.

But although this statement, made by Scarpa, may be mostly true, I am happy to say, that modern experience begins to raise a hope that operations in the foregoing reluctantly inference are possible. Thus Dr. Watson removed from a boy also attacked with retina and lens affected with fungus keratoides almost six months, and no relapse had taken place eighteen months after the operation.—(See Edin. Med. and Surg. Journ. No. 54, p. 51.)

2. The exterior fungus keratoides of the eye, commonly called carcinoma, beginning on the conjunctiva and anterior lamellae, which it is soft, flexible, and juicy, although accompanied with symptoms akin to those of carcinoma, is not actually this disease, till it does become indurated and strictly cancerous; and it is rigid, hard, corneous, sharp, and is very inoperable.

3. The interior fungus keratoides, hard to the touch in all its parts, covered with elevated spots, which has involved the retina of the whole of the eye, and surrounding parts, and rendered the base of the optic nerve, and communicated the sympathetic glands behind the verge of the eye and in the neck, is curable.

4. On the contrary the partial or local extrusion of the eye will succeed when attempted before the malignant fungus keratoides has changed from the state of indolence to that of a scirrhus, crusty, and cartilaginous hardness.—(Vol. cit. p. 308.)

The operation of removing the eye was first performed in the sixteenth century by Barrois, a German, who employed a severely constructed compound shaped like a spoon, with cutting edges, and by means of which the eye was separated from the surrounding parts, and taken out of the orbit. This instrument was too broad to admit of ready introduction in the eye connected part of the orbit, so that when it was used either a part of the disease was likely to be left behind, or the thin lamellae of the orbit to be fractured in the attempt to pass it; many thereby also lost their eyes. Fabricius Hildanus improved these instruments from experience, and in order to avoid them, devised a sort of probe-pointed scissors.—Haller trans. Hist. of Wounds and a pointed history.

FEV

FEV

FEVERS, SURGICAL. Under this head may be comprehended two species of fever, viz. one inflammatory and the other, which are particularly interesting to surgeons, because frequently attendant on surgical diseases.

In treating of inflammations, I have mentioned that a febrile disturbance of the constitution is attendant on every considerable inflammation. In the present article, some account will be given of the particulars of this disorder.

The fever itself is to be described as known, and distinguished by several names; some calling it reflex, others, more symptomatically, and others systematically; it is supposed by some writers to be sometimes constitutional; that is, to originate at the same time with the local inflammation, and from the same cause.—(J. Barrow.) In other instances, and indeed, we may say, in all surgical inflammations, it is symptomatic; or, in other words, it is produced not directly by the causes which originally produced the inflammation, but as consequent on the sympathy of the whole constitution with the disturbed state of a part.

Mr. Trautwein's opinion seems clearly to coincide with those of Mr. Barrow, though differently expressed. He considers constitutional irritation to be of two kinds, direct and reflected; by which he explains, "that the first is widely and immediately derived from the part, and the second is identified with the local mischief, and the constitution has no share in its production."

The second, as the contrary, expresses in a passive or inert state of the constitution, in which the injury or inflammation has given birth, or it may be previously existing. The first is truly symptomatic, never originating spontaneously, and being immediately induced by the local irritation, as capable of being essentially assigned or removed by its removal. The second is essentially purely sympathetic, and being either the cause, then the effect of the local action, is seldom induced by the local treatment. In the first, the local changes are dependent on local causes; in the second they depend on constitutional causes.—(See *Trautwein on Constitutional Diseases*, p. 107.) As the symptoms reflect on the system, if understood in its literal sense, involves the reader in an hypothesis which is perhaps not correct, but not less an advantage in the comprehension of it. Used figuratively, however, it may be as allowable as many other expressions in medical language.

Malignant inflammatory fever is said to be always preceded by chilliness. The sympathetic or sympathetic inflammatory fever sometimes takes place so quickly in consequence of the violence of the exciting agent of the local inflammation, that no preceding chilliness is observable. If, however, the local inflammation be more slowly induced, and consequently system more gradually of the system, then the chilliness is evidently preceded. The sympathetic fever, induced by swelling or tearing a part, is quickly produced, and we have very little time to spend in the critical period of its accession. On the other hand, the sympathetic fever induced by wounds is excited more slowly, and the period of its formation is longer. This fever is not produced when an inflammation may extend to a slight degree; but it follows its appearance if the local inflammation be considerable, or if a violent very movable part.—(Barrow.)

The disorder in which the sympathetic fever is evident, they are altogether beyond the scope of the present inquiry on evidence of the inflammation; but in a great measure, from the degree of the local inflammatory action, accompanied with the various pains and motion of the part affected. Parts in which the action is naturally slow, are extremely painful when inflamed, and the system sympathizes greatly with them. Hence the constitution is very much affected when tooth-ache, burns, or ligatures are the parts inflamed. Severe inflammation of a large joint, every eye being is apt to excite the most alarming, and even fatal development of the system. When very movable parts are inflamed, as, for instance, the eye, the sympathetic fever is generally more considerable than it would be,

were it to come from an equal quantity and degree of inflammation in a less movable organ.

If, however, parts, as muscles, with the tendons, skin, &c., the symptoms will be acute; the pain strong and full, and the heat so of the inflammation be long the heat; but perhaps not so quick as when the part is far from it. The warmth will extend to the head, and the blood will be pushed forward to the most vessels.

If the inflammation be in tendons, ligaments, or long parts, the symptoms will be less violent, the pain with sympathetic more, the heat will not be so full, but perhaps quicker; there will be more mobility, and the blood, not being propelled so well to the vessel vessels, will forward the skin.

It seems to be a general circumstance, that the inflammation be in the upper or lower extremity; that is, far from or near the heart; for the symptoms are more violent, the constitution more affected, and the power of resolution less, when the part inflamed is far from the source of the constitution, than when near it, even when the parts are similar, but is better and true.

If the heart or lungs are inflamed, either immediately or secondarily, by sympathy, the disease has more violent effects upon the constitution than the most sympathy of inflammation would have. If the part inflamed were not a vital part, or one such which the vital part did not sympathize. If the part be such as the vital part readily sympathize with, then the sympathetic action of the labor will affect the constitution as by inflammation of the system. In such cases the pulse is much quicker and smaller, and the heat is more than that of the inflammation with a more part, such as muscle, cellular membrane, and skin.

When the stomach is inflamed, the patient feels oppression and distension through all the stages of the inflammation; the pulse is generally low and quick, and the pain strong, strong, and spasmodic; such is the patient can hardly bear. If the inflammation be not affected, the same symptoms take place, especially if the inflammation be in the upper part of the canal; but if only the canal be affected, the patient is more relaxed, and the pulse is fuller than when the stomach itself is inflamed. When the bowels are inflamed, the pulse is extremely quick and low. When the inflammation is either in the intestines, bladder, or uterus, the pulse generally sympathizes. In inflammation of the liver, the pulse rises more than in the same action of any other part; and perhaps we must, in this instance, give a judgment of the constitutional state than other symptoms than the pulse.

When inflammation is situated in a part, as very essential to life, and sometimes the general affection of the system, called inflammatory fever, the pulse is full and strong; such common, and the blood is pushed further into the surface arteries than when the action is in a vital part. The patient, after some increase of heat, is at first rather cool. The pulse is as above described, when the constitution is strong and healthy; but if this be extremely weak, it will be weak as in many women who had sometimes the pulse may be quick, hard, and small, as in the case of the constitution of the inflammation, just as if the patient were concerned. The blood may also be very, but it will be loose and flat on the surface.—(Barrow.)

The kind of constitution makes a great difference, and as Mr. Trautwein has justly observed, "it is extremely necessary to illustrate the influence of a considerable temperature upon the consequences of some system of disease. Practically, we all know it well. We say, such a person could be a hot patient, as a cold patient, and whoever knows the symptoms of resolving morbid action or suppuration, but under treatment of one and the other case, and knows the impact of this phlogon, and that the greatest degree of mischief is often accompanied by the least constitutional disturbance, and for this reason it seems and most perfectly revealed. The first few hours will enable an experienced observer to determine whether the subject of a serious injury or operation

will do well or otherwise. Here again different is different individuals in the manifestations attending such remote developments as a skin, an enlarged gland, a wheal, or a simple ophthalmia. In some, the inflammation seems general of the affluents, and the individual pursues the ordinary complexion. In others, the whole system sympathizes; the spirits are ruffled; the tongue acquires the opposite tinge; the pulse acquires an undue bound; and the white tongue, the crimson children, and slight erratic pains of syphilitic fever are absent. (Threats on Constitutional Medicine, p. 13.)

We may set down the ordinary symptoms of inflammatory fever, consisting in congestion of local inflammation in common parts and in a febrile habit, as follows. The pulse is frequent, full, and strong; all the secretions are diminished; the patient is violent and restless; the perspiration is obstructed, and the skin is hot and dry; the urine is high-colored and in small quantity; the intellect is purified and the senses sharpened; an oppression chest is experienced; with disturbance of the nervous system, loss of appetite and sleep; and, in some cases, delirium.

SYMPTOMS OF INFLAMMATORY FEVER.

That this part of the subject may little be so to be said, far as it relates to the ordinary febrile disturbance of the system is produced and entirely kept up by the local inflammation, it must be evident that the means employed for diminishing the exciting cause are also the best for abating the constitutional effects. Hence it very seldom happens that any particular symptoms are adopted expressly for the fever itself; as this affection is sure to subside in proportion as the local inflammation is lessened or removed. But within the febrile disturbance is considerable, and the indication itself is also considerable. The slightest state of the system may have more than a share in keeping up and even increasing the local affection, and should be quieted as much as possible. However, in these very instances, in all probability, we should be led to a more express adoption of the antiphlogistic plan of treatment, by an indirect consideration of the state of the local inflammation itself, without any reference to that of the constitution. Indeed, the increased action of the heart and arteries, and the suppression of the secretions, require the employment of anaphrodisiac means and antispasmodics, the very same things which are indicated for the reduction of the local inflammation itself. Bleeding, purging, cold drinks, &c., the subjects of the antiphlogistic treatment, James's powder, or the common acetous powder; and bathing the feet and body in warm water, are symptoms which have the greatest efficacy in tranquillizing the constitutional disturbance, inspired by the febrile inflammatory fever. But I think it right to repeat, that it is hardly what necessary to have recourse to such an exhibition as general bleeding merely on account of the fever; as this is only an effect which invariably subsides in proportion as the local cause is diminished.

As Mr. Thomson has remarked, "the inflammatory fever, depending on external injuries or on chirurgic operations, undergoes a kind of natural crisis by the appearance of suppuration. In these instances, therefore, it is when the patient is strong and full of health, when the disease is seated in an organ of small importance to life, or in a danger of suppuration, as in the case in an inflammation of the parotid gland, that the three great crises of the febrile, the least ought to be used with caution. For we say, by the use of a detraction of blood, produce a sudden sinking of the powers of life, and convert the existing inflammatory symptoms into fever of a different type or character. But in all cases of inflammation in which any detraction with regard to the former general attraction of blood is necessary, it is better, as I have shown as a general rule, that it is better to employ local than general blood-letting." (Lectures on Inflammation, p. 116.)

HECTIC FEVER.

The sympathetic or sympathetic fever already described is an inevitable affection of the constitution, in consequence of some local disease; hetic fever is a remote effect. When hetic fever is a consequence of local disease, it has commonly been preceded by inflammation and suppuration. And there is an ordinary

to produce granulation and contraction; and the cure, of course, cannot be accomplished. The constitution may now be said to be oppressed with a local disease of instance than which it cannot deliver itself.

A distinction should be made between hetic fever arising entirely from a local complaint in a good constitution, which is only described by too great an irritation, and hetic fever arising principally from the bad state of the constitution, which does not dispose the parts to heal. In the first species it is only necessary to remove the part of irritation, and then all will do well; but in the second, nothing is gained by a removal of the part, unless the wound made in the operation is healed, and there is a tendency for the constitution to heal under this state and the operation together, thus under the former disease. Here the great distinction is to be made. (Hector, p. 116.)

Owing to a variety of circumstances, hetic fever assumes various degrees of intensity, and the inflammation, and consequent oppression, become more or less, having the powers of resistance than others, trace more easily fall into this state.

Hetic fever takes its rise from a variety of causes, which have been divided into two species with regard to distant parts, viz. parts called vital, and others not of this nature. Many of the causes of hetic fever, arising from diseases of the vital parts, would not produce this constitutional affection if they were in any other part of the body; such, for instance, is the disease of the lungs, either in, or so situated as to press upon a vital part, or so where functions are immediately connected with life. Sores in the stomach and mesenteric glands, diseased lungs, liver, &c. very soon produce hetic fever.

When hetic fever arises from a disease of a part that is so vital, it commences sooner or later, according to it is in the power of the part to heal or continue the disease. If the part be far from the source of the irritation, the fever will come on sooner with the same quantity of stimulus. When the disease is in parts which are not vital, and causes hetic fever, it is generally in suppuration, where so much resistance happens as to affect the constitution; and where the powers of healing are little. Thus in the case with disease of many of the parts. We must also include some which have a tendency to such specific diseases as are not readily cured in any situation.

Although hetic fever commonly arises from some local disease of a vital part, or from an extension of disease of a convalescent part, yet it is possible for it to be an original disease in the constitution, without any local cause whatever that can be specified.

Hetic is a slow mode of disorganization; the general symptoms are those of a low or slow fever, attended with weakness. But there is rather less action than in weakness; for upon the removal of the hetic cause, the action of strength is immediately produced, and every natural function is re-established, however much it may have been previously impaired.

The particular symptoms are emaciation; a small, quick and sharp pulse; the blood smokes the skin; loss of appetite; frequently a rejection of all aliment from the stomach; want of a great readiness to be thrown into convulsions; spasmodic prostrations, when the patient is heated; pale countenance and very copious urine; and often a constitutional tingling.

Hetic fever has been imputed to the absorption of poisons into the circulation; but so early as the supposition has prevailed in the doctrine which ascribes to this cause many of the bad symptoms frequently attending persons who have sores. When suppuration takes place in particular parts, especially vital ones, hetic fever almost constantly arises. It also attends every inflammation before suppuration has actually taken place, as in cases of white swelling of the large joints. The same quantity and species of inflammation and suppuration in any of the body parts, especially such as are near the source of the circulation, have in general no such effect. Hence, in the first instance, the fever is only an effect on the system, produced by a local complaint that has a peculiar property.

The constitutional sympathies soon readily with diseases of vital organs, than with those of any other parts; these diseases are also in general more difficult of cure than the same affections of parts which are not vital. All diseases of lungs, livers, and kidneys,

ence for 1742, is the account of a child which was shown at one of the fairs, and had six toes on each foot, and the same number of fingers on each hand. In each foot there were six articulated toes, and in each hand an equal number of articulated fingers; but in the right hand there were only five, the only one of which had two articulated fingers, one for the little, and the other for the superfluous finger. In the *Copied Thesaurus*, T. Bartholinus has inserted the description of a very curious skeleton; on the right hand there were seven fingers, on the left six; and besides these contrivances, the thumb was double. On the right foot there were eight toes, on the left, nine; the right metatarsus consisting of six bones, the left of seven. Sydenham speaks of a still more curious case; he saw a man born with at the Hôtel Dieu, at Paris, which had six fingers on each hand, and two toes on each foot; the phalanges seemed as if they were all in a broken, imperfect state.—(Obs. et Cur.) The example of the greatest number of fingers, and toes as recorded by Voigt, including the thumb, there were thirteen fingers on each hand, and twelve toes on each foot.—*Mon. des Anomalies du Corps humain*, t. 3, p. 174. Full details are occasionally met with two thumbs on the same hand.—(Pontrich, *Obser.* 3, Obs. 4-5.)

It is always the individual number of fingers to remain would keep to deformity, and even finger inconvulsion, the surplus is called upon to atrophy them. The rudimentary fingers are sometimes wither away without a nail; but more numerous than one upon each hand, probably situated just on the outside of the little fingers; and, as far as my observation extends, incapable of motion, in consequence of not being furnished like the rest of the fingers with muscles. For the most part the phalanges are also imperfectly formed or deficient. The best plan is to cut off superfluous fingers with a scalpel in the place where they are wanted to the other part of the hand. The operation should be performed while the patient is in the infant state, that is to say, before the superfluous parts have acquired much size, and while the aged can be accomplished with the least pain. The phalanges ought to be made so as to form a wound with edges which will admit of being brought together with strips of adhesive plaster. As soon as the phalanges are applied, the incisions will almost always close without a ligature.

FISTULA. (From *fusus*, to curve around.) A very fine shock in a bone is so called.

FISTULA, in surgery, usually means a sore which has a narrow orifice, runs very deeply, is painful, and has no disposition to heal. The cause is evidently taken from the abscesses which the long cavity of such an ulcer has in fact a pin or rod. A fistula commonly leads to the emission of some discharge, keeping up suppuration; and from which place the matter comes readily escape. No fistulous cure has been more misapplied than this; and no misinterpretation of a word has had more influence in practice than that of the general one. Many surgeons, mistaking abscesses with small openings have for abscesses called fistulae, and being considered as in a rupture, and the treatment pursued has in reality at last rendered them so, and thus the only means of their not having healed.

FISTULA, IN AND, see *above*.

FISTULA LACRYMALIS. Is a very long language, this term has been applied only to one case, viz. that in which there is an abnormal opening in the lacrymal sac, established with any tendency to heal, and from which opening a quantity of purulent fluid is from time to time discharged, especially when the lacrymal sac is compressed. Such has been the confusion, however, respecting the nature of the disease of the lacrymal passages, and so great has been the force of ancient custom, that down to the present time the generality of British, as well as French, surgeons, apply the expression *fistula lacrymalis* to several forms of disease, totally different from each other, and hardly one of which bears name at all applicable. In order not to assist in perpetuating this absurd and erroneous plan, from which nothing but confusion and obscurity can result, I shall follow the example pointed out by Barr, Richman, and our countrymen. Mr. McKim, and consider the various forms of disease to which the lacrymal passages are subject, not under the head of *fistula lacrymalis*, but under the more accurate title, *Lacrimal fistula*, the name of the

FISTULA IN PERINEO. An Sir Astley Cooper has justly observed, increases in the greater generally last, and great facility; a fact amply proved by the frequent results of the lateral operation; but when abscesses are formed in the urethra, either from disordered states of the constitution, and the part together with the lateral abscess, and when they are accompanied with any considerable destruction of the sides of the urethra, and of the corpus spongiosum, they are mostly very difficult to cure.—(Surg. Essays, pt. 2, p. 211.)

When the methods recommended for the removal of strictures (see *Urethra, Stricture* &c) have not been attempted, or not succeeded, patients endeavor to relieve themselves by making a free passage for the urine, which, although it often prevents immediate death, yet if not relieved is productive of much inconvenience and misery to the patient through life. The mode by which patients endeavor to procure relief is by introducing the middle of that part of the urethra which is enlarged, and situated between the stricture and the bladder. Thus the urine becomes applied to a new orifice, irritating the part, and occasioning the formation of an abscess (see which the urine has access; and when the matter is discharged, it is by urine or by art, the urine passes through the abscess, and generally continues to do so while the stricture remains.—A. Cooper, *Surgical Essays*, part 2, p. 210.)

The stricture commonly begins near or close to the urethra, although the stricture may bear a considerable distance from the bladder. The stricture is often induced in the urethra, by which means it is removed, but ultimately this does not constantly happen. The stricture is always on the side of the urethra next to the external orifice.

The internal membrane and substance of the urethra having absorbed, the urine finally gets into the loose cellular membrane of the scrotum and penis, and diffuses itself all over those parts; and as this fluid is very irritating to them, they inflame and swell. The presence of the urine merely in the cellular membrane, from taking place, it becomes the cause of suppuration, whenever it is diffused; and the irritation is often so great that it produces inflammation, not only of the cellular membrane, and afterward in several parts of the skin; all of which, if the patient live, slough away, making a free communication between the urethra and external surface, and producing what are termed *fistulae in perineo*, though it is plain enough to every surgeon who knows the extent of the disease, that a recent opening, produced in the perineum by dissection or abscess, might not be called a fistula immediately it is formed, and at least not until it has acquired some of the characters specified in our explanation of the term *fistula*.

According to Mr. Hunter, when dissection takes place further back than the portion of the urethra between the glans penis and membranous part of the canal, the abscess is generally more considerable.

The urine sometimes penetrates itself into the corpus spongiosum, and is immediately diffused through the whole, even to the glans penis, so as to produce a suppuration of all these parts. A fatal instance of this kind is reported by Mr. C. Bell.—(Surg. col. 184, vol. 1, p. 98.)

Although the location of the urethra may be in the perineum, yet the urine generally passes early backwards into the scrotum, which contains the loose cellular substance in the body; and there it strikes a hardens collecting along the perineum to the scrotum, and in the track of the urethra.—(Hunter.)

Mr. Astley Cooper is of opinion, that as soon as the abscess, which is the forerunner of the fistula, can be plainly felt to contain a fluid, it is the best practice to open down with a lancet. The extensive destruction of parts by dissection will thus be prevented, the place not unfrequently even heals up spontaneously without any further advice being left, and a tendency to those dangerous extravasations of urine is also prevented, which if the abscess be not opened early, often prove destructive to life.—(Ibid. cit. p. 212.)

Dissection can only be prevented by destroying the urethra; but when the urine is diffused in the cellular membrane, the removal of the stricture will probably be too late to prevent all the mischief, although it will be necessary for the complete cure. Therefore, as surgery should be used to pass a bougie, by which the stricture may have been destroyed by the urethra, so

as to allow the instrument to be introduced. When this is the case, ligatures must be placed immediately, in order to procure as free a passage as possible. In these cases, Sir A. Cooper expresses a preference to flexible bougies, the size of which is to be gradually increased until their diameter exceeds the natural diameter of the passage. In some instances, however, he says, that it will be necessary to introduce a pewter catheter, of large size, and to adhere to it, as in the bladder, so as to cover it not upon the structure, and hinder the urine from passing through the perineal orifice. In this manner a permanent cure may often be effected. Although this experienced surgeon agrees with most surgeons of the present day, respecting the general expediency of employing bougies for the removal of a stricture, under the prevailing circumstances, yet he admits that sometimes to proceed gradually, in which, from long use, the stricture and the parts surrounding the stricture are so altered in structure, that no instrument can be passed through the obstruction without danger, and where the slow action of caustics is safer than the use of a metallic bougie. (*Surgical Essays*, part 2, p. 213.) The experience of modern surgeons tends to prove, however, that there are some cases which, from obliquity to the plan of employing bougies or catheters, though a temporary opening may have occurred in the passage. Various cases are the examples in which the aperture in the stricture was the consequence of absorption and absorption, unaccompanied by stricture, and taking place in a bad constitution, and perhaps only preceded by a slight discharge from the ureters. Here bougies would increase the tendency to absorption, and aggravate the local and constitutional irritation. (*id. Cooper*, p. 216.)

While we are attempting to cure the stricture, antiphlogistic measures, particularly bleeding, are to be adopted. The parts should be exposed to the action of hot water; the warm bath made use of; ointments and suppositories made use of; the mouth and in general, with a view of diminishing any sympathetic affection. Say, as Mr. Hunter observes, of these proceedings we often find ourselves, and therefore an immediate effect would be made, both to loosen the bladder, and to prevent the further effusion of urine, by making an opening in the urethra somewhere beyond the stricture, but the better is it the better.

Introduce a bougie, or some such instrument, into the urethra, as far as the stricture, and make the end of it as permanent as possible, so as to be left, week, indred, is often impossible. If it can be left, it must be put upon, and the insertion carried on a little further towards the bladder or ureter, so as to keep the bottom beyond the stricture. This will both allow the urine to escape, and destroy the stricture. When instrument cannot be left in, then by the ligature, we must cut down towards it; and as afterward doing it, proceed as above.

When the stricture is opposite the ureters, as the opening cannot be made in this situation, it must be made in the perineum, in which case, there can be no absorption given by an instrument, so it will not pass unassisted far, and the only guide is our anatomical knowledge. The opening being made, proceed as directed in the cure of a false passage. (*See Croonian, False Passage &c.*) In whichever way the operation is done, a bougie, or a catheter, which is better, must afterwards be introduced into the wound healed over it.

When the inflammation from the introduction of urine is attended with suppuration and mortification, the parts must be freely excised, in order to give vent both to the urine and gas. When there is sloughing, the incision should be made in the mortified parts.

Sometimes, when the urethra is divided, and the cellular membrane of the penis and prepuce is so much destroyed as to produce a phymosis, it is impossible to find the orifice of the urethra.

Frequently the new passages for the urine do not heal, or, in course of the stricture are being removed; and even when they have healed, they often will not heal, but become truly fistulous, and produce more inflammation and suppuration, which often leads to constant suppuration. Such new openings and openings often form in consequence of the former cure having been too small before the obstruction in the urethra is removed.

Really diseases sometimes being an infectious disease, which do not yield to cure, but cause as much as the fistula and course of the urinary have been cured.

In order to cure fistula in perineum, attended with the above-described, urgent symptoms, the fistula must be removed as free as possible, and this alone is often enough; for the urine, finding a ready passage forward, is not forced into the internal mouth of the fistula, which therefore heal up. The cure of the stricture, however, is not always sufficient, and the following operation becomes indispensable.

The stricture is to be laid open in the same manner as other diseases, which leave no disposition to heal. In doing this, as little as possible of the sound part of the urethra must be opened. Hence the surgeon must direct himself to the inner orifice of the fistula, by means of a staff, introduced (if possible) into the bladder, and a probe passed into each of the fistulous passages. The probe should be first bent, that it may more readily follow the turn of the fistula. When it can be made to meet the staff, so much the better; for then the operation can just cut only what is necessary.

When the fistula is so straight, as to admit of a catheter being introduced, this instrument is the best. When neither the probe nor the catheter can be made to pass so far as the staff, we must open the stricture as far as the first catheter will go, and then search for the continuation of the passage, till the purpose of laying it open. The difficulty of this dissection, however, is the thickness, disordered state of the parts in the stricture and perineum, so that as you only lay it open by a catheter, you will have little more the attempt, himself, or sent it made by others. I have myself seen one of the first anatomists in London fix in two instances the continuation of the stricture, and failed in their attempt, therefore, to pass an instrument into the orifice of that passage into the bladder. The difficulty and confusion, arising from the fractured, enlarged state of the parts, which, and so to be cut, have been well described by Mr. C. Bell. (*Surgical Obs.* vol. 1, p. 178.)

Having divided the stricture as high as the termination in the urethra, a catheter should be introduced and worn, at first almost constantly. This is better than bougie, which must be frequently withdrawn to draw the patient in make water, and it often could not be introduced again without being extended in the wound.

In many cases the continuation of the stricture should not be created after a certain period. At that time assists the cure, but, in the end, it may obstruct the healing, by acting on the bottom of the wound, as it is common body.

Hence, when the sore becomes suppurative, as there is danger to the children, and introduced only occasionally. And even after the sores are well, it will be prudent to use the bougie, in order to determine whether the cure is free from disease.

When fistula in perineum have been laid open, the wounds are to be cut first dressed down to the bottom as much as possible, which will prevent the return of the urine and blood, and make the granulations shoot from the bottom, so as to communicate the union by one loaded union. (*Chamber on the Venereal Disease*, ed. 2.) Additional observations upon this subject, and, in particular, the opinions of Desault, will be found in the article *Venereal Abscess and Fistula*. Sir A. Cooper's practice, in cases where a considerable portion of the urethra has been destroyed, will be found in the article *id.* (*See Croonian*.)

FISTULA SALIVARY. See *Fistula Dent.*

FLUTEATION. (From *fluteo* to flute.) The perceptible motion communicated to any collected of pleuritic matter, in any kind of fluid, by applying the fingers to the surface of the cavity, and pressing with them alternately, in such a manner that the finger of one hand must be employed in pressing, or rather in breaking tapping than the rest, while those of the other hand remain lightly placed in apposition to the swelling. When the ends of two set of fingers are thus delicately applied, and the extreme layer of water is moved gently with the fingers of the other hand, the region given forth has a manifestly perceptible vibration, and the sensation thus received is one of the principal symptoms by which practitioners are enabled to discover the presence of fluid in a great variety of cavities. It is according to the touch the perceived fluid in parts, or being excited with the finger, as it is normal, distinguishes the sign of exudation as remarkable, perhaps as any quality that can be applied.

When the collection of fluid is very deeply seated, the fluctuation is frequently exceedingly obscure, and

sometimes not as all disposable. In this circumstance, the presence of the fluid is to be ascertained by the consideration of the symptoms. For example, in cases of hydroceles, ascites, and erysipelas, surgeons do not expect to find the manipulation of the fluid in the thorax with ease; they remember the patient's difficulty of breathing, the tumour extending the lying upon one particular side, the order of the position of the chest, the physical affection of the lungs, the case raised and settled position of the ribs in the affected side, the preceding rigors, fever, and several other circumstances, from which a judgment is formed, both with regard to the presence and the physical nature of the fluid.

PUNCTATION. By a punctation, surgeons commonly mean the application of flannel or canvas, wet with warm water or some medicinal decoction. In the practice of surgery, punctations are made of two or three parts, and sometimes of four, and are made in the following manner. Some punctations are made, however, are used for punctations, with a view of allowing by means of these medicinal qualities, warmth, moisture, and other sorts of a specific action. I shall merely mention a few of the most useful punctations in common use.

PUNCTUM AMMONIACI MURIATICI. R. Rosinam communi ʒij. Alcoholi, m. ʒj. Spirit. Sassa. ʒij.

Just before using the hot direction, add to it the ammoniac resin and spirit. Read to be of service in some scalded blisters; and, perhaps, it might be of use in promoting the absorption of some morbid, and superfluous matters.

PUNCTUM CHAMÆMELI. R. Chamæmeli ʒij. Alcoholi ʒij. Phlegmæ capivi, m. ʒij. A decoction in every common use.

PUNCTUM CINI. R. Pulv. cinis recent. ʒij. M. rosi recent. ʒij. Alcoholi ʒij. Chamæmeli ʒij. A decoction in every common use.

PUNCTUM GALLÆ. R. Gallæ comest. ʒij. Alcoholi ʒij. M. rosi recent. ʒij. Alcoholi ʒij. Chamæmeli ʒij. A decoction in every common use.

PUNCTUM PAPAVERIS ALBI. R. Papaveris, m. ʒij. M. rosi recent. ʒij. Alcoholi ʒij. Chamæmeli ʒij. A decoction in every common use.

PUNCTUM. An instrument which is employed in surgery for a variety of purposes, and having accordingly various constructions. The general design, however, of surgical forceps, is to take hold of substances which cannot be conveniently grasped with the fingers; and, if necessary, the instrument is always formed on the principle of a pair of shears, having two blades, either with or without handles, according to the construction. The smallest handle is that which is employed in the operation of extracting the cranium, and which is used for turning any part of the cranium from the point after the chief part of the operation has been done.

Another forceps, of larger size, is that used for taking up the matter of the arteries, when these vessels require a ligature, in cases of hemorrhage. This instrument is also frequently employed for taking dressings off wounds, removing pieces of dead bone, foreign bodies from wounds, and particularly for securing the blood, which are about to be cut, in all operations where careful dissection is required. This forceps resembles that which is employed in every case of dissecting instruments, and is often called the artery or dissection forceps, from its most important use.

Neither of the foregoing forceps is made with handles; such ones as are used in surgery; and the ends of the blades only come into contact when pressed together by the surgeon.

The following kinds of forceps are constructed with handles, by means of which they are both opened and shut.

1. The common forceps, contained in every pocket-case of surgical instruments, and used for removing dressings from wounds, extracting dead pieces of bone, foreign bodies, &c.

2. Larger forceps, employed for extracting polyp.

3. Forceps of different sizes and constructions, used in the operation of lithotomy, for taking the stone out of the bladder, or for breaking the calculus, when it is too large to be extracted in an entire stone.

4. Drawing forceps, as the common bone-spreaders, and the sharp forceps, made with the edges in the same line with the handles, used by Mr. Lisner for the division of bones.

REACTURE is a situation of continuity of one or more bones, produced in general by internal force; but occasionally, by the powerful action of muscles, as in some amputations in the human body.

The subject of fracture is so interesting a branch of surgery, and the knowledge themselves so important and important, that the title which English surgeons have done for the improvement of this part of their profession cannot but cause equal surprise and regret. Mr. Pott, it is true, made many extremely observations on the treatment of fractures in general, and his remarks on compound fractures in particular are in some respects the best which are extant; but what surgeons will now promise to forget the weak arguments upon which he has founded the doctrine of paying unqualified attention to the mistake of the fracture, as if this were an object which should constantly supersede every other consideration, and invariably regulate the posture of the limb? I have no business in detaching my own mind from the doctrine and practice recommended by Mr. Pott, in regard to fractured limbs, but I shall observe, however, that the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one.

Mr. Pott, in regard to fractured limbs, has made some valuable remarks, and the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one. I have no business in detaching my own mind from the doctrine and practice recommended by Mr. Pott, in regard to fractured limbs, but I shall observe, however, that the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one, and that the doctrine, as it is, is not a new one.

time; 4. Their prognosis; 5. Their treatment; 6. The formation of callus.

The subject will thus coincide with a full account of the symptoms, causes, and treatment of the fractures of particular bones.

1. Differences of Fractures.

The differences of fractures depend upon what bone is broken; what portion of it is fractured; the direction of the fracture; the respective positions of the fragments; and lastly, upon circumstances accompanying the injury, and making it simple, compound, or variously complicated.

1. As to respect to the bone affected.—Sometimes it is one of the long bones, as the humerus, the ulna, or the radius. Sometimes it is a short bone, like the scapula; and far more commonly it is one of the long bones. The position and function of the long bones render their fractures important. The bones of the skull are the only exception to this remark; for they are often broken; but here the assistance of the integument is required less for the sustenance of the continuity itself, than for the affection of the brain, and the extravasation of blood, with which the case is apt to be complicated. Fractures of the short bones are still less common, because these bones, being nearly equal in their three dimensions, are capable of greater resistance, and are not much within the reach of external violence. Besides, most of them are but little exposed to the operation of external force, by their situation, or situation. Hence, except when limbs are crushed, fractures of short bones are generally caused by particular causes, which frequently break the joint, or scapula, and occipital. The long bones, which serve as pillars, or arches of support, or levers, are, from the very nature of their function, particularly liable to fractures.

2. As to respect to the part of the bone broken.—Bones may be fractured at different points of their length. Most commonly, their middle portion is broken, and in this circumstance they usually break like a stick, which has been bent beyond its extensibility by a force applied at each end of it. Sometimes the fracture occurs near, or less near the extremities of the bone, which is always an unfavorable event. Lastly, the bone is sometimes broken in several places, and therefore may be produced by two different causes, which operate successively, or simultaneously, upon the broken parts of the bone; or it may be occasioned by one single cause, which acts at the same moment upon several points of it. These differences of fracture, deduced from their particular situation (says Boyer), are not always of essential relevance; they have a truly important influence over the progress and treatment.

3. As to respect to the direction in which the bone is broken.—A bone may be fractured in various ways, and the fracture produces different issues, according to its direction in regard to the axis of the bone. Thus, fractures are distinguished into transverse and oblique. The obliquity renders the surface of the injury larger, and especially increases the difficulty of maintaining the ends of the bone in contact, after the fracture has been set. Oblique fractures are subject to considerable variety, which depends upon the degree of their obliquity, and whether they are partly oblique and partly transverse. When a bone is broken in different places at once, and divided into several fragments, or splinters, the fracture is termed comminuted.

Boyer has added another class of fractures, viz. longitudinal.—See *Traité des Maladies des Os*, t. 1, p. 357. But such cases were regarded by J. L. Pons as only imaginary, because he conceived that any blow, capable of breaking a bone longitudinally, would which more easily cause a transverse fracture. For the same reason, Lescau absolutely rejected the possibility of longitudinal fractures, and this sentiment has prevailed down to the present day.

The following case, however, is related by Leveillé, in order to prove the possibility of longitudinal fractures. He expressed the faith of an American soldier who was put under his care in the year 1790, in consequence of being struck by a ball in the lower third of the leg at the house of Marseilles. The soldier had washed several times, after receiving the injury, before he arrived at Paris. The wound appeared simple and likely to heal, as soon as the injured portion of the thigh had healed. The event turned out otherwise, and the thigh was amputated.

Leveillé has preserved the thigh, upon which the impression of the ball may be distinguished, and from this point run several longitudinal and oblique lines, which extend from the lower third towards the upper border of the thigh, and pass through the whole thickness of the portions of the medullary canal. They were acknowledged to be really longitudinal fractures, by Boissier, Chappuis, Dumont, Deschamps, and Rivin, who were appointed by the *Académie de Médecine* to prepare the report.—(Gazette, *Journal de Médecine*, t. 2, p. 126.)

In several cases of fractured thigh-bones, there is great violence, which seems under the control of Dr. Cole and myself at Montreal, the same was again longingly to the extent of several night hours. The fact, however, that violence and other have produced longitudinal fractures, is more universally admitted; and even there may doubt upon the subject, a surgeon has been engaged by my friend Dr. Cole, would not permit it. Boyer, who, a few years ago, denied the possibility of longitudinal fractures, in his late work remarks: "In these cases, however, it is not the place of the bone, but the force which is applied, which is the cause of the fracture, which renders it difficult to prevent the possibility of a simple longitudinal fracture."—See *Traité des Maladies des Os*, t. 2, p. 107.

4. As to respect to the respective position of the fragments.—These differences are highly important to be considered, because, as Boyer remarks, the position of the fragments contains almost entirely in itself the prognosis, the displacement of the fragments. It is not to be supposed, however, that such displacement is an absolutely essential symptom of all fractures, as if sudden motion in members supposed of such bones when only one of them is broken. Neither does it constantly happen in every fracture at the neck of a bone, as is especially the case in fractures of the neck of the thigh-bone, the fragments of which sometimes carry their relative situation fully when the patient tries to walk, or the limb is spontaneously moved about. Fractures of the leg are also common, in which there is neither a displacement of the fragments, nor in which the shape of the limb, especially when the thigh bone is fractured near its upper part, where it is very thick. When the thigh bone is broken at its upper part, there is usually every displacement. The only possible position of the fragments having a large interval cannot be separated, or can only be so with difficulty. Fractures of the tibia are also frequently accompanied with displacement. But it is a symptom that almost constantly occurs when both bones of the leg or forearm are fractured together, as, also, in fractures of the tibia which contain only one bone, on account of the little extent of the surface of the fracture, and the great number of muscles which tend to displace them.

The displacement may happen in respect to the direction, length, direction, or circumference of the bone.

As to respect to the direction.—Transverse fractures are the only ones in which this kind of displacement is observed. The two fragments may either be in contact at a part of their surface, or they may not be in contact at all. In the latter circumstance, the limb is shortened by the ends of the fracture slipping over each other.

As to respect to length.—This mode of displacement, in which the ends of the broken bone pass one or two over each other, commonly occurs in oblique fractures, and sometimes in transverse ones, when the distance between the junction of the diameter of the bone has been such that the surfaces of the fracture are in contact. It will be hereafter explained, that whenever this limb is displaced in fracture at the articulation, it is the lower fragment that is displaced.

We may refer to the species of displacement both spoken of, that which takes place in fractures of the radius, ulna, and scapula; but with this difference, that the fragments, instead of passing over each other separately from each other in the direction of the length of the bone, and continue separated by an interspace more or less considerable.

As to respect to the direction of the bone.—In this kind of displacement, the two fragments form a single mass of bone, and the line appears united. It is principally observed in comminuted fractures. It may also happen in simple fractures; for instance, in the leg, where the limb is in a straight position, and the

the open a surface exactly horizontal, and the head is lower than the rest of the limb. The angular projection is then anterior. On the contrary, if the head is posterior, if the limb were too much raised.

In regard to the circumference of the limb.—This displacement series within the lower fragment performs a rotary movement, while the upper one continues stationary. There is fracture of the neck of the femur, if the limb is fully extended by the apparatus, its weight, together with that of the limb and the action of the muscles, will be so extensive, and cause the lower fragment to be drawn upwards.

Besides the simple displacements thus described, there are others of a more complicated nature, which happen in several situations at once. For example, such is the displacement observed in a fracture of the thick bone, when the lower fragment is drawn upwards and upwards, while the limb is turned upwards.

Let us next consider the causes of the displacement of fractures.

The bone, being only passive instrument of locomotion, passive not, in their own organization, any cause of the change of position which takes place; but yield to the action of external bodies, the weight of the muscles, and the action of the muscles.

The displacement may be produced by an external force, either at the moment when the fracture happens, and by the very action of the fracture itself; or it may be caused by the weight of the body when the fracture precedes the fall; or lastly, it may be brought on by some other external force, acting on the fragments, sooner or later, after the occurrence of the injury.

The outward motion, which is productive of a fracture, operates sometimes directly on the situation of the bone of continuity, sometimes on parts of it, as on one distant from the joint. In both cases, the action of the force is not confined to the production of the fracture, but is partly spent in causing a displacement of the fragments.

Fractures are generally occasioned by falls. Sometimes, however, the fall does not happen till after the leg is thigh is already broken. The weight of the body then produces the displacement, by pulling the upper fragment against the seat, which are more or less lowered. This is what happened to Andrew Paine, who, being kicked by a horse, endeavored to get out of the way, but instantly fell down, and the two bones of his left leg, which had been fractured, being impeded by the weight of the body, not only passed through the skin, but even through the socket and bone. After this case a case nearly similar in a young man about twenty years of age, who in a standing posture, was struck in the middle of the thigh with the pole of a carriage, which fractured the femur. The patient fell down, and in the fall the upper fragment was not only driven through the muscles and tendons, but also through the bone.

The weight of the limb itself may produce displacement according to the direction of its transference of the bone, as already noticed. The patient, however, the limb, also, in lifting the patient and carrying him to his bed, may sometimes alter the relative situation of the fragments, and cause them to be displaced.

But of all the causes of the displacement of fractures, the action of the muscles is the common and most powerful one. Among the muscles surrounding a fractured bone, some are attached to the fragments, while length, and are equally considerable both the fragments. Some arise from the bone above, and are inserted either into that which is united with the lower fragment, or into the larger fragment itself. Lastly, there are others which arise from a point more or less distant, and terminate in the upper fragment. The muscles fixed to the thick bone furnish examples of these three arrangements. The triceps is attached to the humerus, the whole length. The biceps, antero-internal, and external, arise from the pelvis, and are inserted into the leg, a part with which the lower fragment is articulated, and all the portions of which it follows. The great head of the triceps is inserted into this fragment itself. Lastly, the flexor, pronator, and supinator, &c., arise from the humerus and pelvis, and are attached to the humerus, not far from the upper end.

The muscles attached to both fragments contribute very little to their displacement. They may, however,

draw them to the side on which they are situated, and thus change the direction of the limb. The triceps, especially in the middle portion, acts in this manner in fractures of the humerus, and renders the thigh convex anteriorly. The antero-internal tendons produce the same effect when the humerus is broken below its middle.

The displacement is principally owing to such muscles as are affixed to the lower fragment, or act with which this fragment is articulated. Suppose the humerus to be broken between its upper end and the insertion of the great pectoral. The muscle, acted by the humerus down, and then up, will draw the lower fragment upwards, and displace it by drawing it on one side of the upper fragment, which remains stationary. In fracture of the neck of the thigh-bone, the upper fragment, included within the capsule, remains, after its attachment is so made. All those which are affixed to the lower fragment, pull it upwards and backwards, in which direction the displacement is irregular. In all fractures, the lower fragment follows every movement made by the part to which it is articulated, and consequently the muscles which are attached to the bones of this part of the limb, become a powerful cause of displacement. Thus, in a fracture of the thigh-bone, the large, antero-internal, and long muscles, draw the leg, and with it the lower fragment, upwards, backwards, and backwards, so as to make the lower end of the fracture below in the inside of, that rather below, the upper end, the extremity of which then projects forwards and outwards. In a fracture of the leg, the gastrocnemius, soleus, and peronei muscles, acting upon the leg, pull the lower fragment of the tibia and fibula, and draw them to the center and posterior side of the upper fragment. For this, as well as every other case, the strongest muscles, in producing the displacement, draw towards their origin the end of the fracture on which they operate. And as the posterior muscles of the leg are far more numerous and powerful than those on the front of the limb, while those on its outside are not so numerous, by any means, the displacement tends to happen in the direction backwards and outwards. Whenever, therefore, a bone is fractured at a given point, a knowledge of the muscles will enable one to anticipate a priori in what direction the displacement will occur, if no force be taken to oppose it, and to prevent altogether from this particular cause.

Lastly, the muscles which are attached only to the upper fragment, may sometimes operate. In a fracture of the thigh situated immediately below the little trochanter, the psoas and iliacus muscles, as they pass, exert a powerful extension of the upper fragment, which elevates the integuments and forms a mass or less considerable projection near the side of the groin. But it is to be observed, that, in general, the displacement of the upper fragment is not constant, and that it is the lower one which is drawn out of its proper position.

The manner in which the displacement of fractures is effected by the action of muscles explains the circumstances which frequently attend these cases, especially fractures of the thigh, clavicle, and leg. This is a thing, a projection of the upper fragment, as it is, which is raised by the bone. One might believe, at first sight, that such projection is formed by the upper fragment, which, passing its natural situation, rises over the lower one. But, on the least reflection, it becomes manifest that the upper end of the fracture projects only because the lower one is displaced and drawn towards that side on which the strongest muscles are situated. Thus, in practice, in order to make the rising end of the bone (as it is termed) disappear, it is only necessary to reduce the lower fragment into its natural place. If, instead of doing this, pressure be made on the projecting part, the danger fails, and if the plate be not more closely pushed and confined, inflammation and abscessing of the integuments and other soft parts, and the conversion of the bone into a compound fracture, are likely to be the unfortunate consequence.

As to the circumstances with which fractures are accompanied.—The most important division of fractures is into simple and compound.

By a simple fracture is supposed a break in the continuity of one or more bones, without any external

sound, communicating internally with the partner, and aimed by the professional at the ends of the traffic line or beam. By a compound fracture, they signify the same sort of injury of a bone or bones, attended with a laceration of the integuments, which laceration is produced by the propulsion of one or both ends of the fracture.

The complex nature of compound fractures will be fully explained in the model of this article; the author indeed has been strongly touched upon in speaking of Amputation.

Fractures are said to be *complicated*, when they are attended with disease or accident, which render the individuals in the treatment more tedious, and require the employment of different remedies, or the pursuit of study operations, for the accomplishment of the cure.

Thus, diarrhea may be associated with severe degrees of dehydration, wounds of the soft parts, the injury of large blood-vessels, a disturbance of the alimentary and purificatory organs of the constitution, as the stomach, intestines, liver, spleen, pancreas, &c., which are said to retard the formation of urine, and render the urine more turbid.

The comparison of fracture with dissolution happens by walking, and it cannot occur unless the fracture has taken place first, or has been produced at the same time with the fracture, and by the same cause. When once the fracture has happened, the fragments are too sufficiently within the grasp of external forces, and are too portable, to admit of the bone being dissolved.

A patient with incontinence may be attacked by an active disease, which may render the treatment more difficult, and the cure slower.

Tolerances of freshwater snails to acid rain

In the first case are comprehended the simultaneous and reciprocal of the bones, the age of the patients, and their situation. Superficial bones are more easily fractured than those which are covered by a considerable quantity of soft parts. The fragments of rib bones resemble those of cancellous bone fractured than others; that the pelvis, which supports the trunk, is more liable to be fractured than the others. The clavicle, which serves to keep the shoulder in its proper position and support as an arched extremity of the motion of the upper extremity, is particularly subject to be broken. The greater volume of the quantity of the phosphate of lime in the structure of the bones, renders them brittle in proportion as no stronger is youth, and, in old men, the properties of the unorganized part is so great, that the bones are fractured by the slightest exertion. In children, the bones are organized upon both a greater principle to the earth, and the bones being consequently more elastic and flexible, are not so liable to be broken as in old men.

whose eye was locked on a person who "looked just like a marriage. Linda, who was voted that season's top player, was not a little surprised to find her eighth-grade experience the same late, one day in the was dramatic her presence in bed. It was then around that she had a power in her mind level. Her self-esteem, so that he knows of the same case in the 1980s film, and Dr. A. Cooper has met with others—some of the

According to Leville, the history of two men is related by Endrager, one of whom died miserably at the age of sixteen, having broken the *Arter* a short time before his death; and the other, after riding his mount very well for two years, and dancing for a year, became affected with rheumatism, and was with one knee swollen as it was barely running along the street. (Nauvoo Doctrine, Chap. 1, p. 160.)

Many extraordinary instances of transverse fusion to meristematic tissue and fragility of the leaves are again noted. Suffice it here to refer to the *Philosophiae Botanicae* of Hermannus Meib. in *Plant. Rorale* Ges. *monstr.* Art. Haidach's, *Epilata*, Nat. Cur. *dec.* 3, *ann.* 5, *obs.* 122; Gooden's *Classical Works*, vol. 9, 343-348; *Observationes* Clair, p. 258; Gmelin's *Institution of Botany*, vol. 1, p. 270, etc.—Observe also *Fraxinus* and *Abies* etc. in *op. cit.*

On the subject of fractures produced by lightning, Linnæus' recommendations as to perfect knowledge in Boreas, Mylius's Observations, Heron de Motte Goussier, Pappart's Works inserted in the Mémoires de l'Académie des Sciences, 1690, and the Treatise published at Vienna, in 1781, by Jean de Boer. The reader would almost wish Lord Apsch's Voyage, in which the effect of lightning in producing the absorption of the vessels of the fractures, and a description of the fragments, is very curiously exemplified.

Paris, Prague, Calicut, and several other cities are known to be a preexisting sites of fissures. This fracture has originated from three regions: from more frequent at the water line, but it is also in rivers, seas, in cold countries, the greater number of falls which happen in winter from the supply and very hard scale of the roads, is a circumstance that fully explains why fractures are then more common than in summer.

The regular cause of fractures in ordinary birds is usually applied in falls, blows, etc. In this instance it is shown the bones were broken by the twisted action of the tendons attached to them. This is almost always the case with the fractured pectoris. The sternum and its ribs have likewise been broken by a violent contraction of the muscles inserted into them. This report is the best. With records 104 individuals, one of which was communicated to him by Forester, and by other men by himself in Malheur La. Presidio & Basadre, who met with the accident in seeking a guide place in the court of the Elbow de Suckow. When the injury happens in jumping, it often has a high curvature. Lewellyn shares a more probable than a portion of the os carpi is torn off by the pressure action of the flexion of the neck, than that it is broken by any blow immediately on the part. He shows that Dremal used frequently to his best complex of the bird, one of which is recorded in his *Clavis* (1847), under

Whether the long bones can be fractured by the mere action of the muscles is yet an unsettled point. In the Philosophical Transactions a fracture of the tibia is ascribed to this cause, and Robertson saw the same accident produced by striking a shankbone with a mallet. According to DeMezurier, it is a man's power, exceeding a labour at a quick rate, his bellows expanded in an expiratory, and his hands violently crossed to assist labour. The consequence was a fracture of the lower third of the leg. Cases inform us that a soldier, after receiving three considerable efforts from himself, then being thrown down by the falling of the ship. The larger vessel fractured by the perpendicular fall of the same vessel of the stage. The last had no fall, and, with some difficulty, supported himself in the other limb till he received assistance.

We are told, says Lottville, by Pease Donnelly, that a negro, about twelve or thirteen years old, was seized with violent spasmodic contractions of the muscles of the lower extremities, that the feet were turned backwards, and the neck of each thighbone was fractured, the ends of the broken bones protruding through the skin near the outside of the

high. A cure was effected after an embolism. We read also, in the *Effluviales Chirurges* about Mathias Chavennard, that during a fit of epilepsy, a child ten years old had its left humerus and tibia broken, and that, upon opening the body, other solutions of continuity were observed. Chavennard assisted in dressing a child, eleven or twelve years old, that had broken the tibia; it was then a considerable distance—*Lancet*, November 1870, p. 104, 208.]

Richardson, however, positively denies that a long time, when healing may even be broken by the mere contraction of the muscles.—(*Obstet. Jour.* 1. 7, p. 15, col. 4.)

For my own part, making all due allowance for the inconsistency of some of the reports made by writers, I think the possibility of the long bones being broken by the violent action of the muscles is sufficiently proved. I have never seen but one exception, but it was a very unusual one. I once attended, for the last Mr. Thompson, an exceedingly strong man, at Pontefract, who broke his *os humeri* in making a powerful blow, although he missed the aim and struck nothing at all. The whole limb was afterward affected with fast swelling and inflammation. This man, I remember, was also visited by Mr. Wellbank, of Clonsbury Lane. According to Nuss, the greatest number of fractures of long bones, by these muscular action, are produced by injury to the broken limbs; and in one of the cases published by this author, not only was this circumstance remarked, but an abscess and effusion of a portion of the fractured humerus ensued. In another instance reported by this gentleman, the clavicle in a state of generalized impurity broke down, was fractured in an effort to carry the arm far behind the back. After the rupture of the fracture, an abscess took place, and a piece of the bone extruded.—(*Lancet*, Nov. 1870, p. 404—406, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.)

3. Symptoms of Fractures.

A point of the symptoms of fractures are equalized; the pain and inability to move the limb, usually exaggerated, may arise from a mere bruise, a dislocation, or other cause. The crepitus, the separation and the equality of the ends of the fracture, when the bone is separated; the change in the type of the limb; and the shortening of it; are circumstances commanding the most certain information; and the crepitus, in particular, is the principal evidence to be depended upon, though occasionally attended on dislocation, and striking, as Sir Assise Cooper has explained, from a change in the quality of the synovial.—(*On Dislocations*, 4th, p. 6.) The signs of fractures, however, are so exceedingly various, according to the bones which are the subject of injury, that it cannot be said, that there is any one which is invariably present and characteristically confined to them. The variety of symptoms of injury, usually since loss of motion in the injured limb, deformity, swelling, tension, pain, heat, or loss, are the general symptoms of fractures. However, it is rarely demonstrable by any one separated with authority, that numerous fractures cannot precede the union of the part, nor occasion outward deformity, and every surgeon must know, that though at first there may be pain in the situation of a fracture, no swelling and tension take place till after a certain period.

When, therefore, a limb is broken, and the events are manifest from the distortion of the part, it is proper to draw near the fingers, the outline of the suspected injury. If it be the tibia, the surgeon examines with his fingers, whether any irregularity can be discovered along the anterior surface, and along the inner edge of that bone. If it be the clavicle, he then traces the muscular movement of the arm, in the same manner. When any unusual pain occurs, or any unusual irregularity appears, he then tries if a gentle or energetic, violent, or light, or undulating motion makes use of the suspected fracture, not against the other. When the ligaments are the subject of injury, it is of course, a positive sign, if the limb is touched; and, in the case of the broken thigh, there is a considerable shortening of the extremity, except in a few cases of fractures, completely transverse. But when there are two bones, as at the leg and the forearm, and only one is broken, the other continues to prevent the limb from being short-

ened and thrown out of its natural range, so that a crepitus can only be felt by a very careful examination with the fingers. The difficulty of the diagnosis is increased when the surgeon is consulted late, and great swelling has come on. "Where is the surgeon," says Bayle, "that has not sometimes hesitated to deliver an opinion in certain cases of this description?"—(*Threats of Med.*, Chap. 1. 3, p. 57.)

When the injured limb is shortened, the surgeon is thus presenting that such change proceeds from the passage of the fragments over each other, even he says that the bones are not displaced, and that the limb is not internally shorter than the other, or as consequence of a previous fracture that has been badly set.

In comparing the length of the lower extremities, one should place the joints in a horizontal position, and put the two external superior spaces of the toes straight in the same line; for, if these processes are not in a level, the limb towards which the joints incline, will seem longer than the opposite member.

The practitioner who is well acquainted with the anatomy of the limbs, and particularly with the mutual relations of the processes of the bones to each other, will readily perceive the alterations produced by a fracture. Whenever, in consequence of a fall or blow, a limb becomes convex at a part where it ought to be convex, or straight, or vice versa; the change of shape and direction must proceed from a fracture with displacement. The inner side of the great toe, when the leg rests on a horizontal surface, should correspond with the inner side of the knee-joint. If this natural relation be altered, if the inner side of the great toe be corresponded with the outer side of the knee-joint, there can be no doubt of the existence of a fracture of both bones of the leg.—(*Wright*, vol. 1, p. 3, p. 25.)

I am aware, that considerable harm and great unnecessary pain have been occasioned in the practice of surgery, by too much reliance to find the extent of fractured bones, and whenever the case is sufficiently evident to the eyes, the practitioner may give way to fluctuation at the expense of better to the advantage. There is no point in the case to be severely considered. A fracture is an injury necessarily attended with a great deal of pain, and followed by heat, is less swelling and inflammation; and to increase these evils by roughly or unconsciously handling the part is a great and cruel, and (if I may use the expression) monstrous, error.

In some kinds of fractures, the broken bone is so surrounded with thick fleshy parts, that it is difficult to find it complete, or ascertain the extent of the injury. Some fractures of the neck of the thigh-bone, surrounded with much extension of the limb, are cases illustrative of this observation. Whether Lazzarini's microscope will become practically useful as a means of elucidating the diagnosis, further trial will experience must determine. Lazzarini is said to have used it with success.—(*See British Med. and Surg. Journ.* No. 78, p. 577.)

4. Progress of Fractures.

The progress of fractures varies, according to the kind of bone injured, what part of it is broken, the direction of the branch of continuity, and what other muscular complications the case. Fractures of bones which have many strong muscles attached to them, are more difficult of cure than those of other bones which have not so many powers attached to them capable of distending the fragments.

A fracture of the middle part of a long bone is less dangerous than a similar injury near a joint. Fractures near joints are attended a false ankylosis. Thus, in a fracture of the thigh-bone near the condyles, the inflammation and swelling extend to the knee-joint, which is affected with a degree of stiffness that continues for a long while, and sometimes cannot be entirely cured during life. Moreover, the inflammation of the joint is attended with great severe symptoms, in consequence of the capsules having been more violent. In a fracture near an articulation, it is to be observed, also, that the ligaments have little concerned over the short fragment, so that it is often difficult to prevent displacement; and with respect to a transverse fracture of the neck of the thigh bone within the capsule ligament, whether an unpropitious position of the process of such a case by means of being matter is to be put back in any business in this country is to be

diagonal joint; and corroborating the statements in the publications of Messrs. Erich, Ambury, and Langstaff, I have still seen in the hand of Mr. Anney Cooper and numerous other surgeons of vast experience, recommending the possibility of a bony union in the permanent kind of osteitis here specified.

When a bone is fractured in several places, the case is more serious, and the difficulty of cure much augmented. But the accident is still worse when a limb is fractured in two different places at once; as, for instance, in the thigh and leg. Here it is almost impossible to reduce the fracture of the thigh, and maintain the reduction well, so as to preserve the natural length of the limb. (*Revue, Traité des Mal. Chir. t. 3, p. 23.*)

Dolipal fractures are more troublesome and difficult to cure than transverse ones, because an oblique surface does not resist the protrusion of the lower portion of the broken bone, and consequently it is very difficult to keep the ends of the fracture duly applied to each other.

Fractures combined with violent contusion of the soft parts, or with a wound rendering them compound, are much more dangerous than others free from such accidents. The best symptoms which render compound fractures in dangerous are many kinds: hemorrhage, violent and extensive inflammation of the limb, high circumscribed, or rising, and fever; large abscesses, disorganization, &c. Fractures of the leg are generally more dangerous than similar injuries of the upper extremities. The wound of a large artery may add considerably to the danger of a fracture.

It is demonstrated that such a fracture is less likely to heal well than that which is clean, or strong, or free from infection. In extreme old age, the view of a fracture is likewise more difficult and sometimes impossible. (*Revue, t. 3, p. 22.*) The severity certainly retards the formation of callus, and, as I have already noticed, even produces an absorption; but it is not true, that pregnancy always prevents the union of fractures. Some years ago, I attended, for Mr. Ransden, a sixty-seven years old man, of St. Paul's churchyard, who broke both bones of his leg when and was several months gone with child. Her pregnancy, however, did not appear to be at all unfavorable to the cure, as she got quite well in the usual time. "It is not generally settled," says a modern writer, "whether pregnancy should be considered a contraindication. I have, as well as some other practitioners, seen a pregnant woman get well of a simple fracture in the ordinary time." (*Journal, Nouvelle Doctrine Chir. t. 2, p. 130.*) And in another place he says, "Cesare Dignon et Faurice de Villiers, l'opérateur en grossesse, ont été les premiers à proposer, en cas de fracture, l'usage du bandage." (*Op. cit. t. 2, p. 178.*) The experience of Bland also tends to prove, that pregnancy is not unfavorable in the union of fractures. (*Revue, Traité des Mal. Chir. t. 3, p. 22.*)

The cases in which fractures have been admitted, will be considered in a future section of the present article.

5. Treatment of Fractures in general.

The general treatment of fractures embraces three principal indications: The first is to reduce the pieces of bone into their natural situation. The second is to secure and keep them in this state. And the third is to remove any subsequent symptoms likely to arise, and relieve them when they have arisen.

The first indication is only applicable in cases attended with displacement; for when the fragments are not out of their relative position, the surgeon must strictly restrict from all avoidable disturbance of the limb. His intervention should then be limited to putting to the fracture, resisting the necessity of any unfavorable symptoms, and removing them, if possible, after they have taken place.

1. Of the Reduction of Fractures.

The means employed for the reduction of fractures in general are chiefly three, viz. extension, counter-extension, and compression, or setting. But, as Boyer remarks, these means should vary according to the species of displacement; and surgical writers have prescribed too much in representing them all three as necessary for the reduction of every kind of fracture. In fact, there are several cases in which extension and counter-extension are perfectly useless; of this nature are fractures of the patella and clavicle, where the

displacement consists of a separation of the fragments. Here the reduction may be accomplished by putting the limb in a position in which the tendons attached to the upper part of the bone are relaxed, and then pushing the upper fragment into contact with the lower.

Extension signifies the act of pulling the broken part in a direction from the trunk, with the view of bringing the ends of the fracture into their natural situation. By counter-extension, surgeons imply the act of pushing extension in the opposite direction, in order to hinder the limb, or even the whole body, from being drawn along by the extending power, which would then be unavailing.

It was formerly recommended to apply the extending force to the lower fragment, and the counter-extension to the upper one. Such practice, indeed, was advised by Mr. Pott, and is still generally followed in this country; but upon his conduct it has been abandoned. The objections made to it by Boyer are, first, that it is frequently difficult, and sometimes impossible, to take hold of the two fragments, as, for example, when the neck of the thigh-bone is broken. Secondly, that by applying the extension and counter-extension to the broken bone itself, most of the particles which surround it are compressed, and such compression produces in them various a spontaneous contraction, which when relaxed, the extension and counter-extension cannot, and cannot even hinder. (*Traité des Mal. Chir. t. 3, p. 34.*) The French surgeons, therefore, apply the extending force to that part of the limb which is articulated with the lower fragment, and the counter-extension to that which is articulated with the upper. For instance, in a fracture of the leg, the extending force acts upon the foot, and the counter-extending upon the thigh; and in a fracture of the thigh, the extension is applied to the leg, while the counter-extending power acts on the pelvis.

One circumstance must here occur to the mind of the surgical reader. In this country, it is properly held, that one of the first principles to be attended to in the reduction of fractures, is to put the limb in such a position as will give the most powerful muscles connected with the broken bone; because these muscles principally impede the reduction, and furnish the ends of the fracture. But, in the French mode of treating the extension and counter-extension, how can the great principle be observed? If the extending and counter-extending muscles are not to be applied to the broken bone itself, but to others which are articulated with it, the first object of necessity is kept in a straight position at the time of reducing the fracture; for when the limb placed in a half-bent state, the extension and counter-extension, as practised by the continental surgeons, would not be in the same line. It therefore, is advantageous to hold the limb at the time of reducing a fracture, the French mode of performing extension and counter-extension must be relinquished. I am not, however, one of those surgeons who are vainly blinded with the idea of the possibility of raising the whole of the muscles connected with the broken bone, by merely bending the limb. On the contrary, I am perfectly convinced, with Desault, that in general, what is gained by the relaxation of some muscles, is lost by the tension of others. But when it is possible to relax, by a certain posture, the set of muscles most capable of preventing the reduction, and disturbing the coaptation of a fracture, that posture I would select. Thus, in a fracture of the leg, the strong muscles of the calf undoubtedly possess this power, and the best position, which relaxes them, appears to me, therefore, the most judicious and advantageous, not only during the reduction, but during the whole treatment of the case. A few years ago I had under my care, in the military hospital at Caen, a fracture of the tibia and fibula, which was at first treated in the straight position. The practitioner who seemed acquainted the fragments, and made them lie tolerably well. But every time the bandage was opened, the bone was always found displaced again. Finding that this circumstance went on for two or three weeks, we resolved to lay the limb on its outside, in the best position. At the head of the bandage was introduced a support to keep the fragments reduced. Indeed, therefore, the situation of a wound, abscess, or some particular disease, indicate an advantage or inconvenience from the straight posture, I always reduce a fracture by it in the best position, which will be hereafter described.

Here, therefore, I consider the French mode of making the extension and counter-extension as generally practicable.

I have also suggested an opinion, that the best position of the limb on its side, as advised by Mr. Pott, was the best for fractured thigh; but this sentiment has extensively appeared in our newspapers, and it gives me pleasure to have this opportunity of declaring my entire aversion to the principles and practice adopted in those papers by Dr. Smith and others, who are the advocates of counter-extending in order the extension were efficient. The considerations which have led me to this change will be related in speaking of fractured thigh. If, then, the surgeon persists in persisting in a mode of broken thigh, I think it will be universally believed, that the parts of the limb recommended by the French surgeons for the application of the extension and counter-extension are the most proper.

The ends and difficulties formerly encountered in setting fractured limbs, especially protruded, in a great measure, from the violent extension and counter-extension practiced by our ancestors. As they were ignorant of the utility of relaxing the muscles which displaced the ends of the broken bone, they had no means but the employment of great force to effect the reduction. Since, however, the excellent instructions contained in Mr. Pott's lecture on fractures have removed all the uncertainties in this, practitioners have generally been careful, in the reduction of fractures, to relax the muscles as much as possible by relaxing them, and thus the necessity for the employment of violent extension and counter-extension is effectually removed.

It will differ to say down, rules respecting the proper degree of force which should be used in making extension; for it must vary in different cases, according to the species of displacement and the nature and extent of the muscles concerned in producing it. In transverse fractures displaced outwards, in the direction of the bone, a very moderate extension suffices, as it is merely pointed with a view of loosening the muscles of the extremity of the fracture, which are always under at least some. For whatever be the direction of the fracture when the fragments pass over each other, the extension and counter-extension must constantly be such as to remove the shortening of the limb, and overcome the force of the muscles which, after all attention has been paid to their relaxation, still oppose the reduction. Extension, however, ought never to be practiced in a violent and sudden way; but in as gradual a manner as possible, the utmost care being taken not to shake, nor even move, the limb any more than can be avoided. When the practitioner extends a broken member all at once violently, he excites the muscles to strong spasmodic action, and there is some danger of lacerating them, because their fibres are not allowed the requisite time to yield to the force which elongates them. The extension is to begin in the direction of the lower fragment, and be continued in that which is natural to the body of the bone.

In every case of fracture with displacement, as soon as the necessary extension has been made, the surgeon is to endeavor to place the ends of the broken bone in their natural situation; this is termed coaptation, or setting. This operation is to be undertaken in different ways, according to the species of displacement, and the position of the ends almost always operates by acting upon the lower fragment, without applying his fingers directly to the broken itself, in order to diminish the contact of the extremities of the bone. Where, however, it is judged necessary for this purpose to touch the broken part itself, it should be done with the utmost gentleness, so as to avoid pressing the soft parts against the sharp and jagged ends.

Although the reduction of fractures may in general be accomplished with tolerable facility, a sometimes happens that the first attempts fail. This is occasionally attributable to the employment of too much force, and too little relaxation, in making the extension, whereby the tendons are injured, and act so powerfully, that the design of the surgeon is completely frustrated. Here the grand means of success is putting the limb into such a position as will relax the most powerful muscles which oppose the reduction. Sometimes, however, the difficulty and obstinate state of the fracture is not the effect of any wrong mode of pro-

ceeding on the part of the surgeon, but arises from the nature, position, and injury, caused by the accident itself. There remains the necessity of making it also the most likely method of removing the difficulty. In short, now that the utility of paying attention to this principle is generally known in the profession, a fracture is hardly ever met with which cannot be immediately relaxed; particularly if a copious bleeding be procured when the patient is a strong vascular subject. This, even when, indeed, will the power, for other reasons, highly beneficial, where the limb is much contracted and swollen, and the venous system is inflammation is great.

7. Of the Means for keeping Fractures relaxed.

After the bones have been put into their natural situation, there then would complete the reduction, were there not in the muscles a continual propensity to displace the ends of the fractured bone. In cases of fractures the muscles are often affected with involuntary spasmodic action, by which the broken part would constantly be disunited, were no measures taken to maintain the extension of the broken bone in contact. Besides, the joints, running through, coughing, sneezing, &c., might thereby subject the limb to a degree of motion by which the coaptation would be altogether destroyed. Hence the necessity of employing means for fixing the broken limb so firmly that it may remain perfectly immovable during the whole time requisite for the union of the fracture. This second indication is sometimes troublesome and difficult, and, as before observed, it is in this part of the treatment that the surgeon has some opportunity of evincing his skill. The means employed for the attainment of this indication are, an advantageous position, splints, bandages, aprons, and various kinds of apparatus.

In the treatment of all fractures, the position of the part, and indeed of the whole body, is a thing of national importance. Whenever the case is well understood, the lower extremities, the patient should be strictly fixed into the radius is completely relaxed. This is an advantage but in the lower bed much more than a yard wide, because the surgeon and assistants can then more conveniently get at any part of the limb. Feather-beds are a great deal too soft and yielding; a horsehair mattress is far preferable. Better, indeed, is an improved with the utility of setting the patient lies upon a surface which will not sink, that he recommends two mattresses to be used, and a board to be laid under the upper one from the hip to beyond the patient's foot.—(Traité des Joints, Chap. p. 22, and 23.)

The most favorable position for a fractured limb is that in which all the muscles passing over the fracture, and extending either to the lower fragment or to that part of the limb which is articulated with it, are equally relaxed. The injured limb should also have firm support at every point, and its position ought to be regulated so that not only that object be perfectly fulfilled, but so the same that the nature of the displacement from the action of the muscles, or the weight of the body, or part itself, may be diminished as much as possible.

The manner as to the most easy position of the limb is that which is usually chosen by a person who posess himself or who is sleeping; for then all nature is extended, and every part becomes that position which is most congenial to it. In this position, the limbs are not extended, nor yet entirely bent; but only to a moderate state of flexion. Hence, Borel remarks, that a half-bent position of the limb is that which is most natural, and that in which all the muscles enjoy an equal degree of relaxation, and, consequently, that it is, generally speaking, the best for fractures. This position which was recommended by Hippocrates and Galen, has been lately revived by Pott, who appears to have comprehended its advantages. Considered in a general way, it is without comparison preferable to every other position of the limb; but its employment should be liable to exception, as will be related in treating of particular fractures.—(See Borel, Traité des Joints, Chap. 8, p. 46.)

In whatever position a broken limb is placed (says Sir William), it should bear throughout its whole length equally and independently upon the surface on which it lies, and not be only partially supported. When, for example, only the extremities of a fractured limb rest upon the bed, the weight of the limb itself will exert a force in the direction of the fracture. The

link will also be rendered crooked, if the broken part be supported, while the extrusion of the link especially, the inferior end, seems by their own weight. The displacement of the fracture is not the only inconvenience arising from the limb being laid upon a surface while it is not every where equally supported. The parts which do bear on this surface experience a painful degree of pressure, which, if long continued, is apt to produce inflammation, and even sloughing, of the adjacent parts. Thus, the pressure of the leg, pressure of the foot that sometimes arises entirely from this cause. Such inconveniences may be prevented by laying a fractured limb on a surface which is depressed there; that is to say, on a surface which is depressed where the limb has projections and rises where it presents depressions. The surface should not be so hard as to injury the patient, yet it ought to be sufficiently firm as to yield to the weight of the limb and appearance. According to Boyer, the best surface for the support of broken limbs are stuffed with clean of straw, a substance which he describes as far preferable to feathers, because it more readily yields of being raised from the place where the limb is placed to another situation where the limb presents a depression or hollow; and it has the advantages of being less heating than feathers and less apt to rot.

If whatever position fractured limbs are placed, they ought to be kept perfectly quiet during the whole time requisite for the union. If the broken bone be moved while the callus is forming the surfaces of the fracture rub against each other, and the progress is retarded; and, indeed, sometimes by repeatedly moving the limbs, the consolidation of the limbs is wholly prevented, or, at least, retarded very slow and difficult.

In order to maintain the limb in the right position, and in a state of quietude, and to preserve the fragments in proper contact with respect to each other, the surgeon is to choose the patient to avoid moving at all more than can be helped, and every carefully to subject the limb to any kind of shock or vibration is to be removed. But in particular, it will be necessary to apply a restrictive apparatus, usually consisting of some application to the skin such, bandages, splints, tapes, straps, and bandlets, &c. (see *See Boyer, Traité des Mal. Chir. t. 3, p. 12*.)

Upon the choice of the bandages, bandlets, &c. which ought to be applied to fractures, no surgeon has written better than Mr. Pott.

"The intention (expressed in applying any kind of external medicine to a broken limb is, or ought to be, to remove inflammation, to disperse extruded blood, to keep the skin dry, moist, and perspirable, and on the same time to afford some, though a very small, degree of restraint or confinement to the fracture, but not to that of pain; and it should also be increased as much as possible in general swelling, as large effusion, or in any disposition to effusion. At St. Bartholomew's Hospital, we use a corset made by a mixture of oil, sugar, and vinegar, which, with soap, and wax, is an excellent dressing for such cases, as it just to afford being spread without warming."

This is very easy, repeat inflammation, is not violent, passes off soon, and very seldom, if ever, increases, or causes either heaves or erysipelas. Before the time and composition of the application made to the limb be what it may, one thing is clear, viz. that it should be put on in such manner, as that it may be removed and added as often as may be necessary, without moving the limb in any manner: it being necessary that when once a broken thigh or the leg has properly set in right, and has been supported properly on the pillow, it ought not ever to be lifted up or moved from its position without necessity, until the fracture is perfectly healed; and it is best that such necessity will not very often occur."

Such application having been made as the surgeon may think fit, the next thing to be done is to put on proper bandages. That formerly used was what is commonly called a cast. This was of different kinds, according to the appearance, shape, or use it was made in the form of any two or three pieces.

By such kind of bandage three intentions are served at, and must to be accomplished, viz. to confine the fracture, to remove or prevent a flux of aneurism, and to regulate the cavity (see *Boisvieux*); but without any other regard to the matter. It will soon be perceived, that although some were of

bandage is necessary in every simple fracture, as well for preserving some degree of situation to the limb, as for the motion of the apparatus, yet some kind of either of these three ends can be answered singly, or even principally, by bandage of any kind, whether cast, otherwise, if this should be found to be true, that is, if it should appear, that whenever kind of situation be made use of, it cannot be a principle, but may be necessary kind of situation, and that is a small degree, and very little to be depended upon. It will follow that such kind of bandage as is most common to be applied with justice and exactitude, such as is most common and out of order, such as would most frequently in need of removal, and in such removal is most likely to give pain and trouble, than to cause any degree and less danger than one which is more easily applied, less likely to be out of order, and which can be removed without moving the limb, &c.

The best and most useful bandage for a simple fracture of the leg or thigh is what is commonly known by the name of the eighteen-band bandage, or rather, one made on the same principle, but with a little difference in the disposition of the pieces. The intention wanted is to make it so that the parts which are to surround the limb make a tight sling with that which transverse the limb; instead of which, if they are tied on so as to make an acute angle, they will fall over each other in an oblique direction, and thereby all power mostly and necessarily, as the parts will thereby have more contact with, and more independence to, shift every. In compound fractures, as they are called, every body will not acknowledge the safety of this kind of bandage, probably in the night, and for very obvious and convincing reasons, but possibly because it does not become necessary to lay up and disturb the limb every time it is dressed, as they have the bandage loose.

The joint attending motion in a compound fracture, the circumstance of the wound, and the extent of degree of swelling of parts thereby produced, are certainly very good reasons for dressing such cases with a bandage which does not render motion necessary; but I should be glad to know what you mean a necessary, or right, or slight, or more a limb in case of simple fracture? what matter can be proposed by it? what injury can be done from it? When a broken bone has been well set, and the limb well placed, what possible advantage can arise from tying it? Surely none; but, on the contrary, pain and possible mischief. Is it not the case that one might be the same instance? Can tying the limb every two or three days continue to such advantage? must it not, on the contrary, obstruct and retard it? Is not perfect quietude an necessary towards the union of the bone in a simple as in a compound fracture? Justice then in the case there is a wound which requires to be dressed, and the motion of the limb may be desired to be avoided with rather more pain than in the other; but does this then in the simple fracture give rise to phenomenon experienced in it?

Every benefit then which can be supposed to be obtained from the use of the common bandage is to be, is equally obtainable from the use of this which I have just mentioned; with one addition, and to the patient still inestimable advantage, viz. that of being able to get to country to have his leg or thigh set, during the cure, removed from the place on which it has been previously depended. (*See Pott's Elements on Fractures, &c.*)

In France a universal preference is given to this kind of bandage in every instance where we suppose the eighteen-band cast, from which it clearly differs in being composed of separate pieces, admitting of removal, so that when a part of the bandage is found to be taken away without changing the whole of the dressings. These pieces are first attached to the limb which are most to be removed, and then they are drawn up to the part. In cases of compound fractures where the bandage is soiled with the discharge it is a very short time, and must be often removed. Certainly Bandage's bandage is the best, particularly as it prevents all the inconveniences common to that of the eighteen-band kind. (*See Boyer, Traité des Mal. Chir. t. 3, p. 18*.)

With respect to the general objects and uses of bandages in cases of fractures, ought to serve two kinds of them, which is strongly indicated in the French sentence; namely, one of "bandaging the fr-

tability of the muscles" by the compression, resulting from their regular and even, suppling to the whole of the member. In describing the treatment of particular fractures, I would like to mention to direct to the examples in which a moderate general compression of the muscles may be attended with utility.

"The parts of the general apparatus for a simple fracture, which come just in order (according to Mr. Pott), are the splints;" which are unquestionably the most efficient of all the appliances made to a broken limb with a view of keeping the ends of the fracture steady and in a proper state of contact. Without these the surgeon would in vain endeavor to treat the reduction.

"Splints," says Pott, "are generally made of paste-board, wood, or some pointing kind of stuff, and are ordered to be applied longitudinally to the broken limb; in some cases, times, in others four; for the better steady and quiet situation of the fracture."

But splints properly made and judiciously applied are very serviceable as beyond all doubt; but their utility depends much on their size and the manner in which they are applied.

The true and proper use of splints is to preserve steadiness in the whole limb without compressing the fracture at all. By this means they become very necessary to use as a curative intention; by this means, they are very capable of drawing pain and other morbid humors at the same time that they support, in the nature of things, contribute to the steadiness of the limb.

In order to be of any service at all, splints should, in the case of a broken leg, reach above the knee and below the ankle; should be only two in number, and should be so guarded with wool, rag, or cotton, that they should press only on the joints, and not at all on the fracture.

By this they become really serviceable; but a splint which extends only a little above and a little below the fracture, and does not take in the two joints, is nearly useless; and, what is worse, it is attended with obscurity.

By pressing on both joints, they keep not only down the two ends, but, by pressing on the muscles, they exercise retain it in its place, so that the fact is, in smaller degree displayed (but they vary, and frequently the discussion thereof, by really pressing the parts covering the fracture against the edges and irregularities of it).

In the case of a fractured os femoris if the limb be laid in an extended position, the splint should certainly reach from the hip to the outer ankle, and another (superior) splint should extend from the groin to the inner ankle. In the case of a broken tibia and fibula, there never can be occasion for more than two splints, one of which should extend from above the knee to below the ankle on one side, and the other splint should do the same on the other side." (See *Remarks on Fractures and Dislocations*, in *Pott's Chirurgical Works*, vol. I. p. 256, 4th. edit. 1809.)

Another very singular discovery of the employment of all tight bandages, and of covering the whole of a broken limb with splints. He was called to a gentleman of rank at Paris, who had broken the knee-joint. He laid the limb upon a coarse splint, the shape of which was adapted to the undersurface of a part of the leg and thigh. No bandage was used; merely two leather straps, which crossed upon the knee, and sustained the fractured bone. "A perfect bony union was thus easily effected. A small afterward extended the use of a coarse splint, applied under the limb, to the middle of the leg and thigh. In the first of these cases, however, only the thigh is removed to the better splint, and from this two branches, or lateral splints, go along the leg. The operation has also a kind of work for the support of the foot. As this simple contrivance is fastened with a very fine muslin, and the pressure on bandages are laid, the surgeon has constantly a view of the whole bone of the limb, and of the fracture part of it, which Amiel thinks a great advantage. In compound fractures, he puts no other dressings on the wound but loose compresses, which are kept continually wet with rose water." (*Mémoires de Chirurgical, Paris, 1806*, 1812.) For further observations on the making, see *Amiel*.

In oblique fractures of the thigh, and sometimes even in those of the leg, the difficulty of accomplishing by the ordinary means a rare this has frequently, and especially without a knowledge of the limb, has led to the idea of employing external extension. This operation implies the operation of a bandage, or fascium, which continually draws the fragments of the

broken bone in contrary directions, at the same time that it retains them from giving over each other, and maintains them in contact during the whole time necessary for their union. In England this practice has long been relinquished. It appears to have been chased away by the leading theory of relaxing every muscle in such tumors as is made it incapable of supporting an oblique fracture; a theory with which the surgeons of this country were but too much misled by the persuasive eloquence of the late Mr. Pott. Doubtless, and, once, however, every indiscretion in the doctrine of the possibility of relaxing the muscles, so as to incapacitate entirely the whole set connected with a broken thigh; and he never ceased to insist on its absurdity; that in such a case the assistance of a mechanical apparatus applied to the limb was the main thing, by which the obliquity of the limb was to be prevented. When we consider the treatment of fractured thighs, we shall find that the principle of continual but moderate extension, has had to Pott's advantage of great extent and influence, though it is a method to which many surgeons in this country appear to entertain strong but highly exaggerated objections.

By means of constant extension (observes Everard), we can very effectually in making the fracture, while the limb preserves its natural length, but we affect the part a dislocation, which is singularly favorable to the treatment of the cancer.

In order to derive from constant extension the utmost benefit, and render the method as little painful as possible, and applicable during the whole term of treatment, the apparatus and bandages, according to Boyer, should be constructed and applied conformably to the following rules.

It should avoid compressing the muscles which pass over the situation of the fracture, and the compression of the whole of the muscles of the limb, which is done by the guiding of the fragments over each other.

With this view, the extending power ought to be applied to that part of the limb which is situated with the lower end of the fractured bone; and the counter-extending force to that which is situated with the upper limb. If these forces were applied to the broken bone itself, the muscles passing over the fracture would suffer such compression as would excite spasm, and render the extension imperfect and even harmful.

The extending and counter-extending force ought to be divided upon as large surface as possible.

The result of this rule is obvious. The pressure of external bodies on parts is less painful, in proportion as the surface pressed upon is extensive, and the operation supported at several numerous points. On this principle a narrow band crosses at right angles and more painful pressure than a broad one; and hence, the rollers and other pieces of the apparatus for making the extension and counter-extension should be as wide as possible.

The power making continual extension should act according to the direction of the axis of the broken bone.

The constant extension should be graduated in its action, gradual, and increasing as a manner as possible.

The machine easily yield is a force which stretches them, when such bodies are applied, and is very gradually increased, according to the motion of the limb, and the power of the muscles producing the displacement. But if not when it is a sudden it begins with making violent extension, the rapid forcible elongation of the muscles would excite such a spasmodic action of them as would frustrate every attempt to restore the natural length of the limb. And if, in order to fulfil this purpose, the extending force were increased in a ratio to the resistance of the muscles, there would be danger of fracturing these organs, because their fibres would not have time enough to yield.

Lastly, the parts upon which the extending and counter-extending force must be applied, and the compression made by the figure, or other pieces of the bandage and apparatus, ought to be equalized.

These indications may be fulfilled by, covering the parts on which the legs and bandages press with one or wool pads; and by filling up all the depressions of the limb with the same soft substances, so as to give it a circular form. The bandages will then rest on the most projecting parts, on which they would make a strong and unequal degree of pressure, if the depressions were not artificially filled up.

By observing these rules, says Boyer, external extension may always be effected, even by the most delicate and inflexible patients; and the important advantage will be obtained of saving the fractures with the proper length of the limb preserved.—(*Traité des Mal. Chir.* t. 2, p. 56, 57.)

F. Means for preventing and removing the unfavourable symptoms liable to arise from Fractures.

After having reduced the fracture, applied a suitable apparatus for maintaining the reduction, and put the part in an advantageous position, the practitioner is to attend to the third indication in the treatment, viz. the prevention and removal of any unfavourable symptoms.

With the exception of a few simple fractures of the upper extremity, it is proper in all cases to allow for the first few days only, very low diet, broths, &c., &c. When the patient is young and strong, and the swelling and inflammation are likely to be considerable, no-nutrition should be prohibited. In other circumstances it may in general be dispensed with, because it is well known, that for the quick formation of callus, starvation is to be avoided, strength and a supple circulation are highly desirable. The patient may be permitted to drink not often and as much as he likes, of any cooling and beverage. A very low diet is only to be continued the first few days, unless great inflammation arise; for experience proves that the method, when too much prolonged, has bad effects, and tends, in the same principle as fasting, to retard the union of the fracture.

Conspicuous is to be avoided by the use of opium and other narcotic medicines. It must be observed, that in fractures of the lower extremity, the disturbance of the limb caused by the patient's being obliged to move himself, after making a paralytic, is seriously objectionable; but perhaps in all, and certainly in some cases, it is useful to open the bowels soon after the accident would have small and pernicious consequences. In order, however, to lessen the difficulty, a cathartic should be carefully introduced under the patient. Here, also, I feel it my duty to recommend to the notice of the profession a very complete fracture-bed, invented by my friend Mr. Earle. One great advantage of this bed, far more of which is moderate, is to enable the patient to read his book, without the slightest change of position or disturbance; an object effected by the simple contrivance of a little kind of trap, covering under the bed, out of which a small portion of the mattress admits of being withdrawn, and a bed is complete is placed for the reception of what is folded from the bowels and bladder. Some great advantages of this apparatus will be hereafter briefly mentioned.

With respect to external applications, we should carefully avoid using all such plasters and cataplasms as irritate the skin or create a disagreeable itching; for they sometimes bring on erysipelas. The simplest aqueous compresses are the best for all simple fractures; and it is the best rather because it does no harm, than because it does any essential good. It is, generally speaking, a good plan for the first few days to wet the dressing with cold water. In this way, the swelling is diminished and swelling may be considerably lessened. The surface, however, should be soiled that the patient should be wet, and may become so much as to do harm if not attended to. No fatigue of the sort of cold water with, make bread-cakes stiff and hard; and as they are perhaps not so efficacious as cold water alone, the latter is sometimes preferred.

When a fracture is well set, the position of the part right, and the bandage well adapted, nothing too tight nor too slack, the less the broken bone is moved, and the less the apparatus and dressings are disturbed the better. Accordingly, however, the practitioner is obliged to take off the splints, and redo the bandage, in order to ascertain that the ends of the fracture do not even extend. We are to turn the splints on the joint two days, or a fortnight, without making any of the important point, be neglected. When the time for alteration, that the fracture was in a state of disorganization, and the limb seriously diseased. Hence, a wrong notion for employing the splint-stuffed bandage, which tends to bring about without disturbing the limb, or even without taking it from the surface upon which it lies, has been proposed.

In fractures of the lower extremities, particularly of

the leg, it sometimes happens the first pain or three nights after the reduction, that the limb is found to be convulsive against the straps, which makes the patient start in his sleep, and displace the ends of the bone, which tend to again reduce.

When the callus has acquired some extent, the patient should still keep the joint or limb quiet, and the union is perfectly consolidated. And in fractures of the lower extremity, even after the union has proceeded so far that the splints which of being left on the patient ought not to venture to get out of bed, or rest upon the limb, till several more days have elapsed.

All fractures, however simple and well treated they may be, are constantly followed by inflammation and swelling of the limb. These unpleasant consequences on the ground, the more violently the limb has been moved, the sooner the fracture is in a joint, and the longer the part has remained motionless and without exercise. The inflammation always affects the interior part of the broken bone much more than the exterior. For the relief of these effects of fractures, it is customary to employ friction, fomentations, vesicating applications, cold washes, and bathing; but sometimes, notwithstanding such remedies, the inflammation does not quickly recover its strength, but remains still and weak for a year, or even a longer time. The most effectual plan for the prevention of this state should therefore be resorted to early. These consist in making the joints rest, the more exact night exercise, as soon as the union is sufficiently advanced not to be in danger of interruption from this position. A great deal of exercise, however, is necessary in making the joint, and it is only by the support to superintend the business itself, that have it to the patient or others. One of the best means for the relief of fracture, weakness and swelling in the limb after a fracture is, to discontinue the splint and tight bandages immediately the state of the callus will allow. The exercise in which the patient is to be made the circulation, and prevent the return of the swelling, is one of the principal causes of the return of the limb; and, consequently, the sooner the patient is set off the sooner will the patient again be free of the limb.

In Fracture, the chief division of fractures is in simple and compound; which last includes many many varieties, the cases which we have mentioned. We shall here briefly notice a few of the complications, and the particular treatment which they require.

Fractures (says Boyer) are always attended with a certain degree of contusion, which is constantly more severe in cases where the violence has acted directly on the situation of the fracture. But such contusion can only be regarded as a complication of the wound, when it exists in so violent a degree as to demand a different treatment from that which is employed in simple fractures.

In this circumstance, the splints and bandage should be applied rather loosely, and the joint ought to be wet with cold water, or some medicinal lotion. The patient is to be bed, more or less freely, according to the state of the constitution, and violence of the contusion. The next day, the splints and bandage should be changed, a thing highly necessary as is observed, for where it has been attended, the limb has been known to mortify, in consequence of the swelling being rendered the bandage too tight.—(Boyer, *Traité des Mal. Chir.* t. 2, p. 52, 53.)

It cases where the contusion is severe, but notwithstanding a wound of the integuments, the wound and swelling may be so intense, that the union is retarded, forming abscesses filled with yellowish matter. These abscesses may derive an interperitoneal suppuration, and tend to imagine that the limb is threatened, or actually affected with gangrene. They ought to be punctured, and covered with plasters of simple emulsion. After some practitioners apply emulsion punctured under the apparatus; but there is a better reason in their use, and perhaps cold lotions are possibly better.

In simple fractures, it does not often happen that a large artery is wounded, but when the injury does occur, and a diffused hæmorrhage takes place, the reason is to expose the vessel by an incision, and apply a ligature above and below the opening. We are to be careful, however, before making the incision, that the patient is not in a violent inflammation, which we

almost always be completed by resident application.

Fractures are sometimes complicated with a dislocation. Here, if possible, the fracture should invariably be reduced before the fracture is set. The possibility of reducing the dislocation (says Boyer), depends upon the species of articulation, the situation of the fracture, and other circumstances of the case. When it is a diaphyseal joint, when the ligaments are lacerated, and the swelling is not considerable, the fracture may be reduced easily enough; but when it is an articular joint, surrounded by numerous muscles; and when the fracture is near the articulation, and situated below the condyles, the reduction of the latter is impossible. The attempt, indeed, would be injurious, because the necessary extension could not act upon the upper fragment; and were it to operate upon the latter, it could only have the effect of possibly stretching the muscles, and perhaps lacerating them. The fracture, therefore, should be at first attended to, and after its firm union, an endeavour may be made to rectify the dislocation. Rarely, however, that there will be some probability of success, when care is taken to move the limb gently, as soon as the state of the callus will permit. He also recommends the employment of constant trituration apparatus. His conclusion, however, that the attempts rarely succeed after the perfect union of the fracture. These are, it is true, examples in which the dislocation may be reduced; but there are cases which are not complicated with a fracture; an accident which always renders the muscles and ligaments so stiff, that they cannot yield at this emergency required for the reduction. "I do not know (says Boyer) that a fracture, complicated with dislocation, has ever been reduced, when the nature of the joint and the various genera of the case prevented the treatment from beginning with the reduction of the dislocation."—(Threats de Med. Chir. t. X, p. 76.)

CONTRAINDICATIONS.

What Mr. Pott has said upon these cases is, with one or two exceptions to which I shall advert, the essence of good surgery, and is the least deteriorated, as a few other parts of his principles have been, by the more mature instructions of time and experience, or by the growing state of surgical science, which, devoted to practice and observation, is continually bringing to light new facts.

In a compound fracture says Mr. Pott, the first object of consideration is, whether the preservation of the fractured limb can, with safety to the patient's life, be attempted; or, in other words, whether the probable chance of destruction, from the wound and circumstances of the accident, is not greater than it would be from the operation of amputation. Many things may serve to make this the case. The bone or bones being broken into many different pieces, and that there is considerable swelling, as happens from lacerated vessels, or other heavy bodies of large surface, passing over or lying on the limb; the skin, muscles, tendons, &c. being so torn, lacerated, and destroyed, as to render extensive amputations the most probable and most extensive means; the extremities of the bone forming a point being crushed, or, as it were, comminuted, and the fragments, meeting each bone lying long and equal, are, as Mr. Pott says, sufficient reasons for proposing and performing immediate amputation.

Mr. Pott admits that apparently desperate cases are sometimes cured, yet that he is so qualified and warranted as to render amputation the only possible means for the preservation of life, we have said this before. This was an uncontroverted fact, but a fact which proves very little against the common opinion, because every case of stupor, also known that what others are very rare, make the rule almost of being made prevalent.

5. This recommendation relative to amputation is of the more importance, because it is most frequently applied to the lower extremities; every instance of delay, in its many instances, in the patient's suffering; and a very short space of time, indeed, frequently makes all the difference between prompt safety and death. If these cases are proved, would admit of deliberation for two or three days, and during that time such circumstances might be expected to arise as might necessitate to determine the propriety of the amputation without delay to the patient's interest, this difference would be

considerable; the former would not seem to be so prejudicial in his determination as he is frequently thought to be; and the latter, being more distressed of the necessity, would submit to it with less reluctance. But, principally for both parties, that it settles the case; and the high expediency having been ascertained, at the moment, the whole decision of a man's judgment is required, that he may neither hastily and unnecessarily deprive his patient of a limb, nor through a false tenderness and timidity suffer him to perish by undeviating to preserve such limb.

The limb being thought capable of recovery, the next consideration is the reduction of the fracture.

"If the bone be not fractured both, the trouble of reducing and of placing the fracture in a good position, will be much less than if the case be otherwise; and in the view of procuring, or throwing both of the bone or bones, the difficulty is always in proportion to the compressive size of the wound through which each bone has passed. In a compound fracture of the leg or thigh, it is always the upper part of the broken bone which is thrust forth. If the fracture be of the femur, the head and the neck large, a moderate degree of extension will in general easily reduce it; but if the fracture be simple, and immovable, as it often does, in a long, sharp point, this point very often makes its way through a wound no longer than just to permit such extension. In this case, the very pushing the leg in a straight position, in order to make extension, drives the neck or spine in and the bone forth, and makes all that part of it which is out of such wound press hard on the skin of the leg underneath it. In these circumstances, all attempts for reduction in this manner will be found to be unproductive; the more the leg is stretched out, the deeper the bone will be buried in the wound, and the more it will press on the skin underneath.

Upon this occasion, it is not very unusual to have necrosis to the skin, and by that means to remove it portions of the protruded bone.

I will not say that this is a way of ultimately mischievous or wrong, but it is more so than is frequently so. In some few instances, and in the case of extreme sharp-pointedness of the extremity of the bone, it may be, and undoubtedly is right.—(See Pott's Obs. on Med. Chir. Trans. vol. 12.) This is every instance it is really necessary.

The two next proper means of considering this difficulty are, change of position of the limb, and enlargement of the wound. In many cases, the former of these, with proper conduct, will be found fully sufficient; and, when it fails, the latter should always be made use of. Whenever we attend to the effect which putting the leg or thigh straight, a compound fracture and protruded bone into a straight position always produces, that is, in the manner in which the wound in such position finds the bone, and in the increased difficulty of reduction thereby increased, and with this, by extending the position of such limb from an extended state to one moderately bent, observe the attention thereby directed both the joint-muscles and tendons, will be satisfied of the truth of what I have said; and of the much greater degree of ease and possibility of reducing in the bent than in the extended position, that is, in the method that is the effect of the state of the case."—(Boisacq, *Principes de la chirurgie*, either by extension or change of position, Mr. Pott recommends an enlargement of the wound.)

"If the bone be broken into several pieces, and any of them be either badly separated, so as to be loose at the wound, or if they be so lacerated and distorted as to render their union highly impossible, all such pieces ought to be taken away; but they should be removed with all possible precaution, without pain, violence, or laceration, without the risk of hemorrhage, and without the risk of the blood being so lost as to be fatal. If the extremities of the bone be broken into sharp points, which pain much and irritate the surrounding parts, they must be removed also."—(See Pott's Obs. vol. 12.) For the whole of this part of the treatment of a compound fracture should be conducted with great caution; and the practitioners should remember that if the parts surrounding the fracture be violated, that it is, in fact, increased, and so directed as to impede the union of the bone, and it is chiefly the same thing as to the patient, and in the case of the arm, the shoulder.

violence be the necessary consequence of the fracture or of the transitory and awkward manner of picking up and disturbing the wound. The great objects of fear and apprehension in a compound fracture (that is, in the first or early stage of it) are, pain, irritation, and inflammation; those are to be avoided, prevented, and allayed by all possible means, in every thing else be as it may; and although certain things are always related as necessary to be done, such as removal of fragments of bone, of foreign bodies, &c. &c. &c., yet it is always to be understood that such acts may be performed without producing as great violence, and without adding at all to the risk, or least necessary incurred by the disease.

Reduction of or setting a compound fracture is the same as in the simple; that is, the reduction in both is to be done, viz. by means of a greater degree of extension to show as yet a position at the ends of the fracture with regard to each other, as the nature of the case will admit, and thereby to produce as perfect and as easy union as possible.

To maintain this place what has already been explained the flesh of the wound, would be tedious and unnecessary. If the arguments there used for making extension, with the hand so moderately bent as to relax the muscles and take off their power of resistance, necessary here in all, they necessarily reach even when applied to the present case; if it is allowed to be feared very much to extend, be it to put it to the test of the simple fracture which are set at all or not slightly extended, and only made in such extension to be picked and irritated, it is considered that it must be much worse when the same parts are torn and separated. After a few additional observations in praise of the good effects of relaxing the muscles, Mr. Pott proceeds:

"The wound, when (if necessary) some pieces removed (if there were any), and the fracture reduced to the best possible position, the next thing to be done is to dress it decently."

When Mr. Pott wrote on this subject, the plan of bringing the edges of the wound together with adhesive plaster, in cases of compound fracture, had not been established; and the advantage of this mode of dressing in the first instance was not fully known. It does not mean the practice of drawing the edges of the wound firmly together with strips of plaster, nor of concealing and compressing the part with the same; but only the method of applying two or three short pieces of plaster, so as lightly and gently to retain the opposite sides of the wound in contact, and afford them an opportunity of uniting by their own force. Now, although such attempts will frequently fail, on account of the wound being generally in a confused, irregular, and inflamed state, the chance of success should be taken, because the experiment in all cases will do no harm, and if it succeed, it will change the case at once, from a fracture with an open wound, to one which has no external communication, or at least almost healed, from a compound into a simple fracture. Some of the following directions, therefore, given by Mr. Pott, I consider in the present state of surgery as only applicable when the wound has healed.

The dressing necessary in a compound fracture, is of two kinds, viz. one for the wound, and that for the limb. By the former, we mean to maintain a proper opening for the way in which the discharge of blood, lymph, matter, excrement, &c. &c. is to be made, and by the latter to support the limb, and by such means, as shall give the most possible pain or fatigue shall enable it to be in a quiet, but open by the part by, not by any means contribute to its cure, or to the discharge of what must be discharged. By the latter we are, should be the prevention of removal of inflammation, in order, if it does not end in all other circumstances, particularly, that the wound may be healed by what we term, and the first intention, that is without suppuration or abscess, without not being prevented by that suppuration and inflammation, or from very large suppuration may be prevented, and which a moderate and steady degree of extension is the best way for the purpose of a cure. The first, therefore, for the dressing for the wound, can consist of nothing better, or indeed as good, as soft dry lint, laid on so lightly as just to support the sides, but neither to draw the wound, nor to the wound and suppuration or inflammation to the discharge of matter. That lint should be kept clear of the edges, and the whole of it should be covered with a piece

spread with a soft watery digest. The dress of dressing must be determined by the state of the wound, if the discharge be small or moderate, more in the first few hours will be sufficient; but if it is large, more frequent dressing will be necessary, so as to prevent, or at least to remove the inflammation arising from a great discharge of an irritating sharp matter.

When, from neglect, some length of time passed without attention, from some cause or accident, as the patient, from awkwardness and inattention in dress, or from any other cause, a tumour has taken possession of the limb, and it is become most painful and painful, Mr. Pott advises, that a warm plaster is the most proper application that can be made, moderate touch is impossible, and every thing which can tend towards relaxing the state, and to cause an easy state of the parts concerned, must necessarily be right. But when the parts are not in this state the intention seems to be very different. To relax the parts, and to remove pain and irritation by some relaxing, cooling, &c. &c. to prevent inflammatory distension, and immediately in every part; and the ought to be done at by very different means. In the former, a large suppuration is a necessary consequence of relief, and the great means of relief in the latter is to cool, and in very moderate degree of it all that is required. The warm-plaster, therefore, although in the best application that can be made use of in the one case is certainly not so proper in the other, as application of a more constant kind, such as mixture of spirit, wine, vinegar and water, with the addition of sweet oil, hyacinthine, acetic acid, sugar plant, ammonia, and medicines of this class, in moderation, the regimen may succeed. By these, in great degree to moderate the inflammation, and with the assistance of what should never be neglected (I mean abstraction) and the general antiphlogistic regimen, inflammation may sometimes be kept off, and a very successful, without any suppuration or discharge of matter."

"Compound fractures in general require to be dressed every day; and the wounded parts are always in the greatest degree of motion without great pain, and quite healthy because no necessary or dangerous dressing."

The common bandage, therefore (the roller) but always of this new broad kind, and which is used the eighteen-lined bandage substituted very judiciously in its place.

Signs of proper length, which reach from one joint, or compound of them both, and are applied on both sides of the limb, are very useful both in the shape and in the compound fracture, as they may, that is, be made to keep the limb from constantly moving and quiet then it can be kept without these."

Mr. Pott then enters into the consideration of the position of the limb, which is so principal a circumstance, that without the concurrence every other will be useless. The points to be aimed at are, the even position of the broken parts of the bone, and such position of the muscles surrounding them, as is most suitable to their wounded, lacerated state, as that is best likely to unite them, by keeping them in the state of it is broken, high inflammation, and at best large suppuration."

According to Mr. Pott, these cases, of all others, are at first the most right observation of the inflammation; just as to be approach, and not to be treated by incision; inflammation is to be prevented by bleeding and aperient medicines. And before the first state or stage, the treatment of the limb must be continued, neither for the purpose of inflammatory treatment by incision, or such as, even and sudden having already taken possession of the limb, were favourable, and relaxing and cooling medicines are required.

"If, then, according to the particular expression of the case, prove successful, the consequence is either a cure only wound, which either begins in the first intention or suppurates very moderately, and goes little or no trouble, or a wound attended at first with moderate inflammation, and then producing large suppuration, with great discharge and inflammation, formation and suppuration of matter, &c. as the other kind of

"The property of having recourse to remission will depend upon the age, season, and general habit of the patient. In the young, robust, and plethoric, the practice is, on every supposition, judicious."

attends do not, second, the suppuration is gangrenous and mortification.

These are the three general results of termination of a compound fracture, and according to these must the surgeon's conduct be regulated.

In the first instance, he has indeed nothing to do but to avoid doing mischief, either by too violent a dressing, or by disturbing the limb. Nature, left alone, will accomplish its own purpose; and art has little more to do than to preserve the free position of the limb, and to take care that the dressing applied to the wound gives no impediment.

In the second stage, that of suppuration and induration of matter, in consequence of large suppuration, all a surgeon's judgment will sometimes be required in the treatment both of the patient and his injured limb. Discharge of the wound, or the mere removal of the dressing, or the removal of fragments of bone, or the introduction of bone, will very frequently be found necessary, and must be resorted to. In the doing this, care must be taken that what is requisite be done, and no more; and that each requisite operation be performed with as little disturbance and pain as possible.

Precious to large suppuration, or considerable collections and indurations of matter, evacuation by phlebotomy, an open limb, and amputations, considered, as well as the free use of anodynes, and such applications to the limb as may assist in the progress of suppuration, are the remedies which Mr. Pott advises for the relief of the swelling, inflammation, and high inflammation, attended with pain, stiffness, and fever. "But the means having been tried, and let out, and the pain, fever, &c., which were symptomatic thereof, having disappeared or ceased, the usual purpose of such measures and such applications cease also, and they cease therefore to be indicated. By evacuation, and the patient's strength has necessarily (and indeed properly) been reduced; by amputation, &c. the parts have been so relaxed as to prevent any contraction or reunion of the soft parts, a substance of foundation, and the establishment of a free suppuration; but these ends were fully and fully answered, another indication arises, which regards the safety and well-being of the patient, namely, if not fully, as much as the former, which intention will be necessarily frustrated by pursuing the method hitherto adopted. The patient now will require support and support as much as he before stood in need of reduction; and the limb, whose internal and external state hitherto required the support and raising position, will now be left by each kind of operation, and would need of such as are equal and contrary qualities, or in some such as shall not violate its state. Good, light, easy supported support, and the Peruvian bark, will best answer the purpose of anodynes, the dissection of the cataplasms, and the application of medicines to the surrounding parts, are no necessary with regard to external."

"Every body who is acquainted with surgery knows (says Mr. Pott) that, in the case of bad compound fractures, attended with large suppuration, it sometimes happens, even under the best and most judicious treatment, that the discharge becomes too great for the patient to sustain; and that, after all the attempts, past and present, which he has adopted, it becomes neces-

sary to amputate the limb by the loss of the limb." This, I say, does sometimes happen under the best and most rational treatment; but I am convinced that it also is now and then the consequence of pursuing the reducing, the suppuration, and the raising plan too far. I would therefore take the liberty seriously to advise the young practitioner to attend diligently to his patient's pulse and general state, as well as to that of his fractured limb and wound; and when he finds all these complaints at an end, and all inflammatory matter and hardness gone, and his patient either languid and prostrated, that his pulse is rather weak and low than hard and full, that his appetite begins to fail, and that he is inclined to vomit at night without assignable cause, and that is consequence of a large discharge of matter from a limb which has suffered great inflammation, but which is now become rather soft and flabby than hard and rigid; that he will in such circumstances be about the support of his patient, and the strengthening of the diseased limb, &c. &c. &c. in which I am from experience, enabled to say often be successful, whereas it may not be generally expected, that he would. Alas! he will have the satisfaction of having made a rational attempt; and if he is obliged at last to have recourse to amputation, he will perceive it, and his patient will submit to it, with less reluctance than if he with trial had been made."

According to Mr. Pott, suppuration and mortification are sometimes the desirable consequences of the treatment done to the limb at the time that the bone is broken; or they are the consequences of the liberation, or pain, made by the mere protrusion of the dead bone. They are also sometimes the effect of improper or negligent treatment; of great violence used in making extensions; of irritation of the exposed parts, by holding off, or in dressing fractures in splinters of bone, or of painful dressings; of improper disposition of the limb, and of the neglect of phlebotomy, anodynes, &c. &c.

"When such accident as such disease is the more consequence of the injury done to the limb, either at the time of or by the fracture, it generally makes its appearance very early; in which case also the prognosis is generally too rapid for us to check. For these reasons, when the mischief seems to be of such nature that gangrene and mortification are most likely to ensue, no time can be spared, and the impending mischief must either be prevented, or prevented by early amputation. I have already said, that a very few hours make all the difference between probable safety and destruction. If we wait till the disease has taken possession of the limb, even in the smallest degree, the operation will serve no purpose, but that of accelerating the patient's death. If we wait for an apparent abatement in the part, we shall have wasted time all opportunity of being really serviceable is past. The disease takes possession of the cellular membrane surrounding the large blood-vessels and nerves some time before it makes any appearance in the integuments, and will always be found to extend much higher in the survey part than its appearance in the latter seems to indicate. I have mentioned once or twice the experienced mark of suppuration, often a gangrene has been known, that I never saw it cured; it has always been found the patient's destruction."

As far, however, as my experience will enable me to judge, or as I may from thence be permitted to dissent, I think where that mark appears, should never be made, but the first opportunity having been neglected, or not sustained, all the power of the therapy

"After the bones had tested, Mr. Pott never found it necessary to amputate a limb for a compound fracture, on account of the bad green discharges."

In the article *Gonorrhea* I observed, however, the reader well that there is a species of gangrene, arising from external violence, and totally unconnected with constitutional causes, where the surgeon should devote from the common rule of deferring amputation until the mortification has ceased to spread. A treatise on *Suppurative Processes*, which was published a few years ago by Baron Larrey, contains the most decisive facts in regard to the propriety of such practice.

—(See also *Mr. de Cley's Memoirs* &c.) The experience of Mr. Lawrence seems also to confirm the truth of Larrey's observations. —(See *Med. Clin. Trans.* vol. 8, p. 164, &c.)

"It is a positive evil, says, from a liability in using a knife, to make use of knives and pliers convenient for the discharge of large matter. Where matter or a discharging sinus immediately and safely to make, it is always preferable, the surgeon sometimes among themselves agree to the operation with which it is applied, and maintaining as the judgment by consulting the matter; however, which, it requires a greater degree of power to make it efficient than a limb in such circumstances generally can bear."

"It is surprising how large and very dangerous a discharge will be made to a considerable length of time, in some instances, from the efforts and irritation of a splinter of bone. It therefore such discharge be made, and there be neither signs nor judgment to account for it, and all other circumstances are favorable, sometimes about always be made in order to know whether such cases does not exist, and if it does it must be gently and carefully treated."

viability of the bones is more active; these vascular granules, their pulsation substance there abundant. On the contrary is advanced age, the parts have lost all disposition to develop the vascularity of the bones is in a great measure obliterated, and (as the expression of Boyer) their vitality is annihilated after the union of fragments of bone which avulsion is them.

It has been assumed, that in early infancy the callus is generally produced in excess, and may sometimes be its impediment. His experience does not confirm the truth of this statement. The real cause of delivery always proceeds from the fact, either being badly set, or not kept properly reduced, or vice from the part being pushed about before the union has acquired a due degree of firmness.

2. *Classification.* A fracture is united again sooner in a strong healthy person, than a weak unhealthy subject. Sometimes, the consolidation is prevented, by some hereditary unknown cause, nothing wrong being perceptible either in the constitution or the part. Hirsch and Van Keulen met with several cases of this kind, in which the patients were apparently quite healthy and laboriously trained; and there are few examples of such experience who are not acquainted with similar examples.

3. *Thickness of the Bone, and Weight which it has to support.* The bones are thicker and larger, in proportion as they have a greater weight to bear, and as the muscles inserted into them are more powerful. It is observed, natives purchase, that the larger the bones are the longer is the time requisite for their union. Thus a broken thigh-bone is longer in growing together again than a fractured shin; the shin longer than the humerus, the bones of the forearm, clavicle, ribs, &c.

As the callus remains a good while softer than the rest of the bone, it follows, that if the newly united bone has to bear all the weight of the body in walking, the patient should bear this extreme longer. Hence one reason why fractures of the arm are sooner cured than those of the thigh, and why six or seven weeks at least are necessary in the treatment of a broken thigh-bone, which of itself has to support in proportion all the weight of the trunk.

4. *State of Health.* Fractures heal with more quickness and facility when the patient enjoys good health. The system has a more and powerful effect in restoring the consolidation of fractures, and even in causing an absorption of the callus several years after its formation, so that a bone becomes flexible again at the point where it was formerly broken. As Lord Apsley's fracture the phenomenon is particularly marked.—(See p. 112, 113, 15, in this.) Lamachus is acquainted with several cases, in which the callus at the end of eight weeks became again soft and the bone flexible, as consequence of the patients being attacked with gonorrhea or syphilis.—(See p. 113, 1, 2, 3, 4.) Cannon, has venerea, and syphilis are also stated by several writers to obstruct, and sometimes hinder altogether, the formation of callus.

Falkner has cited two cases, which tend to prove that the union of fractures is retarded by pregnancy.—(See p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.) Another has also cited a case in which the union, which had been delayed during pregnancy, took place after delivery.—(See p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.) And (see p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.) Another has published an account of a fracture of the radius in a pregnant woman, where the cure was apparently retarded for a long time by this circumstance, but through the timely care of the patient to deliver, the callus was not very firm till after that event.—(See p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.) From the facts, however, mentioned in a preceding page of this article, there can be no doubt that pregnancy frequently does not prevent the formation of callus in the ordinary case, though the observation of Mr. Wesley is true, that many instances have been observed of bones being fractured during pregnancy, and never showing any disposition to unite till after delivery.—(See p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.)

Whether the present trade here and is a genuine pair, as the owner presenting the name of fractures, a few additional observations to the same nation will be introduced in the sequel of this article, when we have of the nature of the various degrees of all the

2. Of some local Circumstances necessary for the Consolidation of Fractures.

As Boyer has well explained, three local circumstances are necessary to obtain a firm union without adhesions. 1. The two fragments must be possessed of sufficient vascularity. 2. The surfaces of the fracture must correspond. 3. They must be kept in a satisfactory unobscured state.

The two fragments must be sufficiently vascular. If one of them should be too much supplied with blood, the fracture would be incapable of union. This, as is asserted by Boyer, though denied by Albrecht and others, is what happens in certain fractures of the neck of the femur, where the head of this bone is extremely detached, and the ligamentous substance which is attached over its neck, and serves as its periosteum, is totally lacerated, as well as the vessels which run along it. Hence, the upper fragment lodged in the osseous cavity no longer receives from the vessels sent to it through the ligamentum femoris a sufficiency of blood for the purpose of the formation of callus. This is especially likely to be the case when the patient is the advanced in years, and the vessels considerably lessened in number. An adequate circulation must therefore exist in both portions of bone; or without it the attempt at union will fail.

The surfaces of the fracture must correspond exactly. This circumstance is not absolutely necessary for the consolidation of the fracture; but without it the formation of the callus is always slow and difficult. For instance, in a transverse fracture of the thigh-bone, the fragments, after being displaced according to the thickness of the bone, may undergo a second displacement according to its length, by passing beyond each other. The surfaces of the fracture are then set in all in contact, and the portions of bone only touch each other by their sides, which, being covered by the periosteum, can unite with difficulty. Here, at the end of the second month, the union will frequently have made but little progress; we can the cure be accomplished without difficulty and shortening of the limb.

The fragments must be retained in a completely immovable state. This condition is so essential to the formation of callus, that if the ends of a fracture were daily moved, they could not unite. The two extremities of the bone would then heal separately, just like the ends of a wound which have not been put in contact. The ends of a fracture, however, which unite frequently become according to Boyer's always become smooth, and in three ordinary any capillary ligament formed.—(See p. 113, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.)

3. Different Opinions as to the Formation of Callus.

As Boyer remarks, perhaps no subject has excited more discussion than the formation of callus. The opinions mentioned in the introduction of a physician that which was called the osseous mass, and which, becoming hard, served to unite the ends of the broken bone, just as glue serves to unite two pieces of wood. Hence, in order to favour the production of callus, they were in the habit of accumulating their patients in an atmosphere of every sort of stercoraceous aliment, the glutinous parts of animals, and especially of mussels, at which Falkner's patients refuse to eat.

But if these accounts were true, callus must be inorganic, or else one would be compelled to admit, that the organization of an inorganic fluid was capable of producing an organized substance; which is an absurdity. Besides, observation demonstrates that callus is an organized matter, like the substance of the bone itself, which it resembles, and that when subjected to anatomical and chemical experiments, it exhibits all the appearances of the proper substance of bones.

According to Haller, callus is formed by the part system, which he regards as the origin of ossification. When a bone is fractured (says this naturalist), the periosteum of the two fragments first grows together, and then unite, and form a cartilage rising round the fracture. The thickened periosteum is converted into a gelatinous substance, which soon becomes a cartilaginous matter. In the vessels of the periosteum, and different points of ossification commence, which finally unite. Then, when every part of the periosteum near the fracture is hardened and united, the matter is changed, as it were, into a sort of clay, which spreads over the two fragments, and binds them together.

separated ends are necessarily in mutually parallel, I can conceive it possible (says Mr. Lawson), and, in fact, have frequently been seen to be connected with the soft parts; but this was the presence of a granular matter which had still retained its vitality, and which, instead of forming a contribution to the general action, grew powerfully, not only in the periphery, but also in the removal of bone, have been long allowed to the periphery. No one, I will venture to say, has as yet noticed this membrane in either of these cases. Now bone has not been found adhering to the periosteum, either in fractures of morrons; far less have complete substance composed of the ossified periosteum been ever developed enclosing a neoplasm. In every instance the new formation is deposited in nodules adhering loosely to the soft bone, with an irregular, above, freely perforated by capillary arteries. The vessels of the bone, in short, are ramified on the external and internal periosteum; but it is only after their entrance into the periosteum, that they become disposed to join and ossify matter."—(Edin. Med. and Surg. Journ. Vol. 76, p. 67.)

From experiments continued by Brocher and Williams, it would appear that the union of broken bones is not exclusively owing to the effusion of a particular fluid which coagulates and gradually changes into an osseous substance; nor to the contraction of the myofibrils and oblique periosteum; nor, in the majority of instances, to granulations produced from the surfaces of the fracture; but it is frequently dependent upon all these circumstances together, or at least several of them; and, in every case, it is the result of a series of changes, observable in the soft parts immediately adjoining the fracture, in the periosteum, in the medullary sheath, in the cartilage and very texture of the bones themselves, and in the substance intervening between the two fragments. As simple fractures, the following are stated to be the principal circumstances resulting during the process.

1. Effusion and coagulation of a small quantity of blood between the ends of the fracture, which blood escapes from torn or ruptured vessels.

2. A fluid, at first of a thick quality, effused and accreted, as it were, between the periosteum and the bone, and thence exuding from the surfaces of the fracture and the soft parts.

3. A gradual increase in the quantity and consistency of the preceding substance, changed together, forming every day a stronger and stronger connection between the parts; then their change is a red osseous substance between the fragments, and between the bone and the periosteum to a substance which is at first soft, but in the end acquires the characters of bone.

4. At the fractured part, a reunion of the periosteum and soft parts, which are equally contracted and adhered together, with the intermediate substance between the fragments.

5. A distention, and then an obliteration of the medullary cavity, at first by a cartilaginous, and then a bony deposition.

6. Successive modification of the whole of the enveloping composing the callus, and of the substance between the fragments, preceded by a fibrine and cartilaginous state.

7. The return of the soft parts around the fracture, and their fit of the periosteum, to their natural state.

8. After the union of the surface of the fracture, the medullary cavity and texture are gradually re-established, and the swelling formed by the callus always diminishes.

First, in compound fractures, besides these circumstances, the production of granulations from the surfaces of the bone is also to be taken into the account.—(See Edin. Med. and Surg. Journ. Vol. 58.) This difference from what happens in the process of union of simple fractures is also particularly noticed by Mr. Wilson.

"From the joint being exposed in a compound fracture, the first bond of union, viz. the coagulable lymph of the blood, is removed or destroyed; hence it can become vascular. Inflammation is consequent on the injury done to the periosteum, and when the parts are healthy, granulations arise. These granulations from the broken extremities of the bone soon assume the osseous appearance, and when they come in contact with each other, union."—(On the Structure, Diseases of the Bones, &c. p. 223, 2nd Lond. 1820.) It is curious that, in broken cartilages, we

never see a mass of bone; a circumstance which has often been noticed in respect to the ossification of the ribs.

Whatever may be the process by which union is formed, it is during the first two or three weeks after the fracture that the fragments undergo the changes which produce their reunion. But it is between the twentieth and thirtieth, and especially between the thirtieth and fortieth days that nature labours most actively in consolidating the callus. Hence, in this period, care must be taken the ends of the fracture in contact and perfectly at rest, should be maintained; for, though there are a few instances in which deformity really proceeds from irregular consolidation, it is a fact, that the deformity almost always originates from the fracture being disturbed and not kept properly reduced.—(Reper. Trans. du Med. Chir. L. 2, p. 84, &c.)

1. Of the Contact to be adopted in the ordinary Period of the Consolidation of Fractures, and of the Treatment of Joint Injuries.

When the requisite time for a broken bone to become firmly united has elapsed, it is proper to examine carefully and carefully the place of the fracture, in order to learn whether the union has acquired a suitable degree of strength. If the bone should be found to be in the best of the injured parts, the callus is not sufficiently strong, and the limb should be immediately put up in the apparatus again, with a view of preventing a new fracture, or, at all events, deformity.

For the same reason, the patient should not be allowed to make much use of his limb, so soon as the fracture has united. In fractures of the lower extremity, he ought to use crutches, and only let the weight of the limb be borne by the upper part of the injured limb. Then, as the strength of the callus has been known to be completed, the limb is to be straightened, and the patient becomes a cripple. An accidental slip may also produce the fracture again; for, notwithstanding the insertion of wires, the callus is far from being stronger than the rest of the bone, it is still considerably weaker.—(Reper. L. 2, p. 94.)

If, when the necessary time for the completion of the union has elapsed, the callus is not yet firm, we must examine, let the relative position of the fragments and the consistency of the callus, &c. The cases which may have retarded its consolidation.

That the state of the constitution has considerable influence over the process by which broken bones are restored, is unquestionable. Schneider found the formation of callus, even in the most simple fractures, sometimes delayed eight months, and in one instance more than a year; but the patients were all of them remarkably healthy.—(Vermischte Chir. Schriften, p. 1, p. 28.)

There are certain indelible constitutions, in which bones, more particularly, however, the os humeri, will not unite again after being broken. These temperaments are also very various; at least I infer so from two subjects to whom I paid particular attention. One was a strong, robust man, whose chief peculiarity seemed to be his indifference to pain: the ends of his broken humerus were cut down too, lashed out, and saved off, by Mr. Long, in St. Bartholomew's Hospital, and the limb was afterwards put in splints and taken the greatest care of; but no union followed. The other case was a broken tibia and fibula, which remained divided for about four months; but afterwards joined together. The latter subject was a complete instance of hypochondriasis. I afterwards saw a woman, under Mr. James Esdaile, in the above hospital, whose os tibiae did not unite in the least, though it had been broken several months. Every attempt to move the bone occasioned excruciating torture. The woman died of some illness in the hospital, and on dissecting the arm, the cause of the fracture not having united was found to arise from the lower, sharp, pointed extremity of the lower portion of the broken bone having been forcibly driven up by the accident, and protruding the substance of the tibia, in which it still remained. I was indebted to Mr. Esdaile for the description of the appearance in the dissection, and I do not know this kind of impediment to the union of a fracture has been noticed by any other writer than Mr. Charles White, who appears to have ascertained the possibility of the occurrence.—(Lancet in Surgery, p. 76, vol. 1776.)

The causes of fractures remaining divided will

The foregoing treatment, however, is only likely to answer before a new point, in all events, a ligamentous division occasioning is completely healed, and when the limb has attained its former position.

When the case is old, and there are grounds for believing that a permanent union of the ligamentous connection has taken place, we are advised to cut down to the ends of the bone, strip of saw them off, and then treat the limb just as if the case were a recent compound fracture.

This last practice was first suggested by Mr. C. White. "Robert Elliot, of Bolton, in Lancashire, a very beautiful boy, nine years old, had his right arm, about midway in the year 1780, by a fall from the ladder, torn the middle of the bone. He was immediately taken to a bone-setter in that neighbourhood, who applied 3 bandages and splints to the arm, and treated him as properly," says Mr. White, "as I suppose he was capable of, for two or three months. His situation, however, went by as means productive of the desired effect, the bone not being at all united. A surgeon of eminence in Manchester was afterwards called in; but as he was found to be of no service to him, and as the case was very curious, he advised the lady's friends to send him to the Infirmary at Manchester. He was accordingly brought thither six Christmas following, and admitted an in-patient. Upon examination, we found it to be a simple oblique fracture, and that the ends of the bone were not only at: his arm was become not only entirely motionless, but even adhered to him, and was likely to be otherwise as there was little probability that it could ever unite, it being now six months since the accident happened."

Amputation was therefore proposed as the only method of relief; but I could not give my consent to it, as the boy was young, and had a good constitution, it was hardly possible that it could be owing to any fault in the nature of fluids, but that either nature was disappointed in her work, by frequent motion while the callus was forming, or rather, that the fibres ends of the bone, being strong, and divided a part of a muscle, and some portion of it had probably lacerated itself between the two ends of the bone, preventing their union. Whichever of these might be the case, I was of opinion," continues Mr. White, "that it might be relieved by the following operation: viz. by making a longitudinal incision down to the bone, by bringing out one of the ends of it, which might be done with great ease, as the arm was flexible, and cutting it off either by the saw or cutting pliers; then by bringing out the other, and cutting off that likewise, and afterwards by replacing down end to end, and treating the whole as a compound fracture."

The objections made by the other gentlemen concerned to this proposal were, first, the danger of wounding the humeral artery by the blade. Secondly, the laceration of the artery by bringing forth the ends of the bone. And, thirdly, that we had no authority for such an operation. As to the first, that was easily obviated, by making the incision on the side of the arm opposite to the humeral artery. The place of incision appeared to me to be at the external and lower edge of the deltoid muscle, as the fracture was very near to the insertion of that muscle into the humerus; the danger of wounding the vessel not only being by that means avoided, but also the operation, while the patient was confined to his bed, the matter could be prevented from lodging, and the wound be easily come at, to remove the dressings. The second objection will not appear to be very great, when we consider that in compound fractures the bone is frequently thrust through with great violence through the integuments, and seldom attended with laceration of any considerable artery; and as this would be done with great caution, that danger would appear very trifling. The third and last objection is in every thing a groundless one.

This method which I have been proposing," says Mr. White, "was at first conceived upon, and I assisted in the operation, which was performed by a practitioner of great abilities in his profession, on January 31, in the present year (1790). The patient did not lose above a spoonful of blood in the operation, though the dissection was not made so deep. When the operation was finished, the limb was placed in a fracture-box, covered on purpose, the lid confined to his bed, and the rest of the treatment was being different from that of a compound fracture."

The wound was nearly healed in a fortnight's time, when an erysipelas came on, and spread itself all over the arm, attended with some degree of swelling; this, by dressings and the antiseptic method soon went off, and the cure proceeded happily, without any other interruption. In about six weeks after the operation the callus began to form, and is now quite firm. The arm is as long as the other, but somewhat smaller, in consequence of such long-continued bandages; he daily regains strength in it, and will soon be fit to be discharged."—(Case in Surgery, p. 58, &c.)

In another instance of a broken arm, which continued divided an extraordinary length of time, Mr. White performed an operation somewhat similar to the foregoing one, with complete success. He made a longitudinal incision, about four inches in length, through the integuments which covered the fracture. By the application of a trephine, he cut off the upper end of the bone, and so the lower end could not so easily move off; he continued himself with scraping it. In the course of the subsequent treatment he had occasion to take off, under the cutting pliers, a small angle of tibia, and to touch the lower part of the bone with the hammer of anatomy, so that he was able to introduce the same vessels between the extremities of the fracture, in order to destroy a substance which intervened. A trifling inflammation followed. In twelve weeks the bone was firmly united."—(Op. cit. p. 81, &c.)

Respecting Mr. White's cases, there are now some other instances upon record, where the operation which he first proposed has succeeded. In the year 1812 Langenscheidt operated upon a humerus in the foregoing manner, and the result was perfectly successful. The united fracture was situated at the insertion of the deltoid."—(New Med. J. 1, p. 105.) Mr. Rowlands, of Chester, by a similar operation, cured a fractured thigh, which had, till all disposition to unite."—(See Med. Clin. Trans. vol. 2, p. 47.) Vigani, surgeon to the Hotel Dieu, at Toulouse, has also practiced Mr. White's operation with success."—(See Leroy, Mem. de Chir. Militaire, t. 2, p. 124.)

On the other hand, the operation has frequently failed. In the instance in which I have just mentioned the humerus by Mr. Leve, in St. Bartholomew's Hospital, it did not answer, though the ends of the bone were most firmly sawed off, and the case treated with particular care and skill. Boyer states that he once performed the same operation in a similar case; but that it had not the desired effect."—(Traité des Mal. Chir. t. 3, p. 180.) Dr. Physick, of New-York, when he was a student in 1785, saw this proceeding successfully adopted in a case where the humerus remained divided."—(See Medical Repository, vol. 1, New-York, 1804.) Besides these examples, I have heard of others, in which Mr. Elliot, Mr. Green (Med. Clin. Review, Feb. 1826), and Lord. Med. Gazette p. 237), and other practitioners, have tried the experiment with no better success. What is still more degrading, the operation has sometimes proved fatal."—(Richardson, New-York, Clin. J. 2, p. 24, of 2. Leroy, Mem. de Chir. Militaire, t. 2, p. 124.)

The difficulties, the danger, and the frequent ill success of the foregoing operation, rendered another mode of treatment extremely desirable, when Dr. Physick, of New-York, suggested the plan of introducing a wire through the potential joint, with a view of exciting inflammation, and bringing about a union of the bone. This suggestion promises to be a considerable improvement in modern surgery. In Physick had an opportunity of performing the new operation on the 15th of October, 1805, in an example of divided humerus, twenty months after the occurrence of the accident. Before making the incision above Dr. Physick, I desired the assistants to make some extension of the arm, in order that the wire might be introduced, as much as possible, between the ends of the bone. Some ligament a plectrum was applied to the surface made by the wire, and secured by a roller. The patient suffered very little pain from the operation. After a few days the inflammation (which was not greater than what is commonly excited by a similar operation) through the first of my other part) was succeeded by a moderate suppuration. The arm was now again extended, and again applied. The dressings were renewed daily for twelve weeks, during which time no amendment was perceived; but soon afterwards the bending of the arm at the fracture was observed, and it became very rigid.

been, and the patient complained of much more pain than usual, whenever an attempt was made to hold it at this place. From this time the formation of the new bony union went on equally, and on the 4th of May, 1852, was so perfectly completed, that the patient could move his arm in all directions as well as before the accident happened. The wound was now cured, and the small scars occasioned by it healed up entirely in a few days. On the 29th of May, 1852, he was discharged from the hospital perfectly well, and he has since repeatedly told me his arm is as strong as ever it was." (*Phy. Med. Rep.*, vol. 1, New York.) In the *London Medical Repository* for Aug. 1852, a case is also noticed, in which Dr. Fyfe cured an ununited fracture of the lower jaw by means of a pin.

On this subject an interesting memoir was read by Larrey to the Ecole de Médecine at Paris (*Gazette Méd.*, 1811). It was entitled, "Dissertation sur la non-union de quelques fractures, et en particulier de celles du bras, et sur les moyens nouveaux de guérir les fractures articulaires qui en résultent." The author of this problem admits, that when he was at Ayrberg, he saw Baron Percy, then with the army of the Rhine, pass a wire through the imperfectly healed centre of a compound fracture of the thigh, which fracture seemed to have lost all disposition to unite. The method answered so well, that in two months the patient was able to walk without crutches.

Mr. Hodge has also successfully employed the pin in a case of ununited broken thigh. The patient was a boy about 15. (*New Med. Lib. Trans.*, vol. 5, p. 267, &c.) In this country the same operation has been performed for the cure of a disunited humerus by Mr. Stenfield, of Leeds. (*See op. cit.* vol. 7, p. 108, &c.) It appears, also, that Mr. Charles Bell applied the method to a fracture of the leg, at the time when it was in England. The patient was a child six years old, and the broken bones had continued without union three years. Thomas had been originally mistaken by other skillful surgeons for a mere contusion. Here, however, whether the operation succeeded or not. (*Phil. Med. Lib. Trans.*, vol. 4, p. 185.)

We must not forget, however, that Dr. Fyfe's new operation will succeed in every instance. Like most other surgical means, it is liable to occasional failure, among which, I believe, we may include the strong union on a detached thigh by Mr. Wardrop (*New Med. Lib. Trans.*, vol. 8, p. 265), though a partial union only is mentioned. In a case recorded by Mr. Anstey, the wound did not cure. Mr. Hinchman was also obliged to take out the screw because of irritated hæmorrhoids, and go home without it. (*New Practical Obs.*, p. 162.) Three instances of failure were seen by Mr. Anstey (*Obs. Fracturae*, p. 254), and an additional one has been recorded by Mr. Kain. (*New Med. Lib. Trans.*, vol. 15, p. 185.)

In the same case, and also in another which I now under this gentleman's care, the plan of cutting down to the ends of the fracture, and rubbing them with creosote potash was tried, but without success.

Instead of several of the foregoing wires and often uncomfortable pins, Mr. Anstey has tried, with much encouragement, the influence of local pressure and rest. He maintains the ends of the fracture closely pressed together, the process, when the fracture is transverse, operating longitudinally; and when oblique, transversely. A short sling, pads, and a particular apparatus are used accordingly. (*Obs. Fracturae*, p. 226.) Mr. Dechamps, of Huel, has related two cases, in which a union of the fracture followed a powerlessness in the application of fracture of bone. (*On Fractures*, p. 75.)

[This brings to its ingenuity and skill of our countryman, Dr. Fyfe, is without doubt well merited, for the use of the seton in cases of artificial joint has found adherents in almost every country, and been attended with great utility and success. In particular failure, however, has led to the trial of local pressure by Mr. Anstey; and in the *London Med. and Phys. Journal* for 1852, Mr. Hodge has reported an instance of the success of this practice, after the failure of the seton. Dr. Thos. H. Wright, of Baltimore, and Dr. Wilson, of Philadelphia, have each reported successful cases of Mr. Anstey's treatment of ununited fractures, and promises to go on to give the place of the seton in this country among surgical generally. Dr. Wright's case may be found in the *Ann. Journal of the Med. Society* for 1852.—*Edin.*]

FRACTURES OF THE ORAL BONE.

These bones, from their situation, are much exposed to fracture. The fragments are sometimes not damaged; but most frequently they are depressed. In order to replace them the surgeon must pass a bone elevator, a ring-headed screw, or any such instrument into the cavity, and using it as a lever, push the fragments upwards; while, with the index finger of the left hand, he prevents them from being pushed too far. When the fragments are depressed in all directions again, some authors advise inserting them with an elastic pin outside, so that, introduced into the cavity, but I am inclined to believe, with Mr. F. H., no pin can be employed so as to support the broken bones; and when these have been replaced, they will not readily change their position, as they are acted upon by no muscles. (*New Operative Surgery*, &c., p. 229.)

Besides, as Deland remarks, since the teeth sustain much the fragments, they cannot support them, and they must be secured with all the instruments of surgery, bodies placed in contact with parts already damaged, or about to become so. (*Précis des Méd. Lib.*, &c., p. 302.)

As fractures of the lower jaw are the result of falls, and direct blows on the face, the soft parts are always either very much contused or wounded.

Fractures of the lower jaw are sometimes attended with very dangerous symptoms; depending either on the compression of the brain, produced by the same blow which causes the fracture, or on the soft parts being pushed into the cavity of the mouth, or on the fragments being driven into the brain, so as to injure and compress the brain. This last danger, however, some modern surgeons consider as not of frequency; and whatever the symptoms are, as a solution of the brain, the nature of the case is referred to the intimate connection between the bones of the jaw and the os frontis. (*Phy. Med. Lib. Trans.*, vol. 4, p. 185, &c., p. 186.)

When there are symptoms of pressure on the brain (*see Med. Lib. Trans.*), and the time has been lost, depressed, the surgeon must immediately raise them, and endeavor to disengage gradually the perpendicular process of the os maxillare, which is connected with the external maxilla and os frontis. Perhaps a pair of curved canines, or a pair of curved forceps, introduced into each nostril, might facilitate the surgeon to do what is necessary. Bleeding, and the antiphlogistic treatment are always proper; for the vicinity of the eye renders it liable to become inflamed; and when there are symptoms of pressure of the brain, emaciation, &c., the necessity of such practice is still more strongly indicated.

FRACTURES OF THE LOWER JAW.

This bone is sometimes fractured near the chin; but seldom so as to produce a division of the symphysis; the fracture is generally happening between this part and the insertion of the masseter. In other instances the fracture occurs near the angle of the jaw, that is to say, between the insertion of the masseter and the root of the coronoid process. The last may also be broken in two places at the same time; in which case the patient's position is extremely difficult to keep right, because many of the muscles which draw the lower jaw downwards are attached to that part.

The cricoid and os hyoid are sometimes broken; the former the most frequently.

Fractures of the lower jaw may be either perpendicular to the base, oblique, or longitudinal: of the latter, examples have been known, even in a portion of the alveolar process, with the teeth in it, was detached from the rest of the bone.

The soft parts are generally contused and wounded. J. L. Petit mentions one case in which the bone was broken, and the coronoid process quite detached, by the kick of a horse.

Fractures of the lower jaw are seldom in displacement in the following way. When the fracture is at the symphysis, the side on which the process maxillaris is situated is drawn downwards and backwards by the sub-maxillary muscles, while the other fragment is supported by the muscles which close the jaw. When the fracture is more backwards, no displacement occurs in the same way, but one or more of the teeth are fractured in two pieces, the middle portion is always pulled downwards and backwards by the muscles attached to the chin, while the two

lateral pieces are kept up by the levator subulae. When the ramus of the jaw is broken, the masseter, being attached to both pieces, prevents any considerable degree of displacement. When the neck of the condyle is fractured, the pterygoid muscles may pull the condyle forwards.

When a blow is received on the lower jaw, or the bone is injured by a fall, or by the pressure of some heavy body; when an arrow-point is embedded in the part, and no lamina is left to fill in the loss of the bone, when some of the teeth, corresponding to that inequality, are loosed than the others; and when a crevice is perceptible on joining the two pieces of the jaw as with plaster; there can be no doubt of a fracture. When the pieces are impacted, or the bone disabled by a wound, the case is (if possible) still more manifest.

Fractures of the mandible produce great pain near the seat, particularly when the jaw is moved; and a crevice may also be felt.

Fractures of the lower jaw, whether simple or double, are easily set by passing the displaced part upwards and a little forwards, and then passing in the ends of the bone, so as to bring it exactly on a level with the portion which has preserved the natural position. Indeed, the correctness of the reduction can always be rightly judged of by attending to the line which the line of the jaw ought to form, and observing that the neck of the teeth is as regular as before will allow. The best means of the reduction, however, is difficult; and can only be well executed by supporting the lower jaw, and keeping it applied to the upper one. As the latter instrument cannot be properly applied in persons whose teeth are very irregular, it is sometimes necessary to introduce an even piece of cork between the teeth on each side of the mouth, and against this rock the lower jaw is to be kept up with the bandage previously secured, while the aperture left between the osseous in the situation where no teeth is placed, allows food and medicines to be introduced with a small spoon.

As soon as the fracture is set, the surface should always have thin parietal plaster, previously wet and thickened with vinegar, to the outside of the jaw, both along its side and across its front. Over this plastered parietal a bandage with four turns is to be applied, the centre being placed on the patient's chin, while the two extremities take care to be placed to the front part of a napkin, and the two anterior ones fastened by a part of the same napkin across backwards. When the parietal plaster becomes dry, it forms the most convenient apparatus imaginable for supporting and supporting the fracture. A piece of soap-plaster may now be applied to the teeth underneath, which will prevent any dislocation of the hardness and pressure of the parietal plaster.

Had the bone been merely cracked, the patient should be allowed only such food as does not require mastication, and it may be given by means of a small spoon, introduced between the teeth. Rootes, soups, jellies, tea, and other fluids appear most eligible.

In order to keep the middle portion of the bone from being drawn downwards and backwards towards the larynx, it is frequently necessary to apply tolerably thick compresses and under and behind the chin; which may be well supported by the bandage already described.

I need hardly state the necessity of joining the pieces as soon as setting, or moving the jaw more than can possibly be avoided.

When the condyle is fractured, as it is uncommonly

drawn forwards by the action of the pterygoid muscles, and on account of its deep situation cannot be pushed back, the lower portion must, if possible, be pushed into contact with it. For this purpose the bandage must be made to operate particularly on the angle of the jaw, where a thick compress should be placed.

Compacted fractures of the lower jaw are to be treated on the same principles as similar injuries of other bones. If possible, the external wound should be healed by the first intention; and when this attempt fails, may must be taken to keep the wound clean by changing the dressings about once in three days; but not often, lest the fracture suffer too much disturbance. It is observed that compound fractures of the jaw, and even simple ones, which are followed by abscesses, are particularly liable to be succeeded by troublesome and tedious exostoses.

In very bad fractures, in which all motion of the jaw must have the most pernicious effect, I consider it prudent to administer every kind of nourishment in a fluid form through an elastic gum catheter, introduced through one of the openings down the oesophagus.

Now and then happens that fractures of the lower jaw become situated: Dr. Pagnan's successful treatment of one such case with a seton I have already noticed.

Fractures of the Vertebrae.

On account of the shortness and thickness of these bones, they cannot be broken without considerable violence. The spinous processes which project backwards are the most exposed to such injury; so they are the weakest parts of the vertebrae, and most superficially situated. On this account it is possible for them to be broken without any mischief being done to the spinal marrow. The fracture, which is gross enough to break the bodies of the vertebrae, must produce a greater or less extension or other mischief of the spinal marrow; from which almost such more pernicious consequences are to be apprehended than from the injury of the bone abstractedly considered. The displaced parts of bone may press on the spinal marrow, or even wound it, so as to occasion a paralytic effusion of all the parts which derive their nerves from the continuation of this substance below the fracture.

Mr. Astley Cooper divides fractures of the bodies of the vertebrae with displacement into two classes; first, those which occur above the third cervical vertebra; and, secondly, others which happen below that bone. The first class, he says, are almost always immediately fatal, if the displacement be to the great extent. In the second description of cases, death takes place at various periods after the injury. The reason of this difference is ascribed to the circumstance of the pressure being exerted from the third and fourth cervical parts, whereas in the first class of cases death is taken, almost produced by paralysis of the diaphragm, and the stoppage of respiration. (On Dislocations, p. 520.)

As the more common of the more easy to detect symptoms which very much resemble those usually occurring when the vertebrae are fractured, the diagnosis is generally obscure. An inequality in the line of the spinous processes, and a crevice may sometimes be distinctly felt. The lower extremities, the rectum, and bladder are generally paralytic; the patient is afflicted with retention of urine and stool, as with an involuntary discharge of the latter. (Ibid.)

If the lower vertebrae be displaced, the lower extremities are rendered so completely insensate, that they may be pinched, burnt, or blistered without the patient suffering any pain. The pain at such cases is generally erect. In general, also, according to Mr. Astley Cooper's observations, patients with fractured lower vertebrae die within a month or six weeks; but he knows of one patient that lived two years, and then died of gangrene of the nates. In fractures and dislocations of the dorsal vertebrae, the symptoms are very singular; but the paralysis extends higher, and the abscess becomes more frequently infected. Death commonly follows in two or three weeks; but Mr. Astley Cooper mentions one case, in which a gentleman enjoyed the northern climate. Fractures of the cervical vertebrae, below the origin of the phrenic nerve, occasion paralysis of the arms, though it is seldom complete. Sometimes, when the diaphragm is relaxed, one arm is more affected than the other. As the ribs

* (Dr. J. Blane, Baron, of Philadelphia, to whose account of skulls I have had frequent occasion to allude, has devised a bandage for fractures of the jaw, to which a preference is now generally given in this country, as well for its simplicity as, judging the fragments in a state of compression for the facility with which in securing the dressings, and in applying to wounds of the face and other. He observes with "a roller an inch and a half wide just before the prominence of the chin, and continues it obliquely over the centre of the fractured bone across the fracture of the jaw and ear, and carries over the zygomatic arch, under the chin, and passing the same direction on the opposite side and is as tight as the back of the hand; he then passes it obliquely around and parallel to the base of the lower jaw over the ribs; and continues the same degree on the other side until it ends where he commenced, and repeats."—Ibid.)

costal muscles are paralytic, great difficulty of respiration prevails. The abdomen is also considerably inflated. Death generally follows in from three to seven days.

Mr. Andrew Cooper notices the following as the appearance fitted in the direction of each vessel. The spinal process of the damaged vertebra is depressed; the anterior process is fractured; the body of the vertebra is broken through; the segment very tapering in the intervertebral substance. The body of the vertebra usually projects forward as an arch or an inch. Between the vertebra and the sheath of the spinal marrow blood is extruded, and frequently on the lower part itself. When this effusion is slight, the spinal column is compressed and inflamed. When greater, it is torn by the bony arch of the vertebra process, and a ridge is raised at each end, but the dura mater contains whole.—(See A. Cooper on Dislocations, &c. p. 328, &c.)

Fractures of the spinal processes without other serious mischief are not dangerous, and are the only instances of fractures of the vertebra which admit of being treated with certainty.

Any attempt to set fractures of the bodies of the vertebrae, even with the known or exact, would be both useless and dangerous. General treatment can alone be employed. Opiating will tend to prevent inflammation in the structure of the injury. When the patient is allowed with a liberal diet, the inflammation, swelling, hemorrhage, &c. the body may be rubbed with camellia oil, and purgative elixirs and antispasmodics given. If requisite, the spine may be supported with a castor. When the bladder, rectum, and lower extremities are paralytic, it is common to rub the back, loins, extremities, and limbs with liniments containing the Chinese oil.—(Bayer.) With respect to the external and internal use of stimulants, however, it can never be judicious, when there is reason to apprehend much inflammation of the injured parts; and as for the blood thus entering the nervous system, there can be little rational reason, the cause of the inflammation being here of a mechanical nature.—(Bridges, Med. Obs. t. 3, p. 222.)

Some authors recommend depressing, or turning out a portion of the fractured bone, when the compression of the spinal marrow is injured by a splinter is suspected; but, according to my judgment, the indication can never be sufficiently plain to authorize the operation, which, on account of the great depth of the intervertebral and parts, must be very tedious, and even difficult to effect, without a great risk of increasing the injury which the spinal marrow may already have received. An unsuccessful operation of this kind was once performed by Mr. H. Chase, and quoted by Mr. Tyrrell.

Some cases, published by Mr. C. Bell, tend to prove that the danger to be apprehended from injuries of the vertebrae of the spine is that which accompanies injuries of the brain. Hence, he joins the possibility of suppurations in recommending general and local bleeding, and keeping the patient perfectly quiet. And, with respect to operations for the removal of fragments of bone, it is his decided belief, that an incision through the skin and muscles covering the spine, and the withdrawing of a portion of the shell of bone which surrounds the marrow would be extremely fatal; the membranes of that part being particularly susceptible of inflammation and separation. And even if a sharp spear of fractured bone had run into the spinal marrow, and caused pain at the lower part of the body, Mr. C. Bell thinks that exposing the medulla to extract the fragment would so aggravate the mischief, that inflammation, suppuration, and death would be the inevitable consequences.—(Surgical Obs. vol. 1, p. 157.)

The same author describes inflammation of the spinal marrow as attended with its above mentioned nervous crisis, which is particularly followed by excitement of the brain in this manner, heat is poured into the sheath of the spinal marrow, and vitæ by its poisonous contained filer, or by its infection, destroying the functions of the part so as to be attended with the same consequences. The excitement of the brain being followed by effusion, death ensues.—(Id. 169.) Cases are also referred to, where palsy of the lower extremities occurs on several months after an injury of the spine, owing to thickening of the membrane of the medulla, or disease of the latter part itself. How Mr.

C. Bell recommends previsions in local bleeding and deep incision.—(P. 169.)

A fracture of the processes dorsales seems instantly fatal, as happened in the example mentioned by Mr. A. Cooper.—(On Dislocations, &c. p. 343.) In the practice of Mr. Elliot, a case occurred, in which a leg with a fracture of the atlas lived a year after the accident.—(A. Cooper, op. cit. p. 343. See also J. T. Sherrington, Remerciement after Polytraumatisme and Shock des Joints, Gazette des Hôp., 1820. F. J. P. Garroble, Des Mal. Chir. internes, Casus. Scissurationis Vertebrae Thoracis Fractura costalis, postquam Extremities a viris diti Symptomata delinquentia duxerit Septimum Junius, Argent. 1761. Cases of Fractured Spine, London, vol. 2, p. 35.)

FRACTURES OF THE STERNUM.

The sternum is not frequently broken, and the removal of this fact is required at the position of this bone resting, as it were, upon the cartilage of the ribs, and also in some instances to its spongy nature. When the accident does occur, it is from the direct application of external violence to the injured part; and never the fracture is always accompanied with great mischief, or even a wound of the sternum, and more or less injury of the thoracic viscera. As Bayer remarks, the sternum, in consequence of the elasticity of the cartilages of the ribs, may be readily pushed back by pressure in this direction; and the result is a natural change in the form, and a real dislocation, if it does. Now, since this cavity is always supplied filled by its contents, three situations cannot happen in a considerable and sudden manner, without a risk of the thoracic viscera being crushed and even ruptured.—Thus, when the sternum has been fractured in violent blows in the chest, the heart and lungs have been found to be severely contused, and sometimes lacerated, and there will always be positive danger of such mischief, when the fracture is attended with depression of one or more of the fragments. In some cases, a large quantity of blood is effused in the external portions of the anterior mediastinum; and, in others, the air is followed by inflammation and suppuration in the same situation, and necrosis of the broken part of the bone. Since the lungs are also liable to be injured by the same force which causes the fracture, it would be the depressed pieces of bone, especially may become another complication, as we are exemplified in a case related by Pajon.—(Collected Observations, &c. at Chap. t. 2, p. 214, &c. Rome, 1820.)

A fracture of the sternum is rendered obvious by the inequalities perceptible when the surface of the bone is examined with the fingers; by a depression at the site of the broken piece; a swelling, and an unusual soreness of the injured part in respiration. In many cases, the fracture may be seen, the soft parts being torn or otherwise wounded. The healing is difficult, and mostly accompanied with much effusion of blood, suppuration, and liability to form the look according to the observations of Pott and Haller; several of these latter symptoms may continue, with less intensity, a long while after the fracture is cured.—(Lewell, Nouvelle Méthode Chir. t. 2, p. 343.)

Fractures of the sternum, when more extensive, and, of course, only require common treatment; viz. a piece of soap-plaster to the situation of the injury, a rib band the chest, quietude, bleeding, and a few opium with a view of preventing what may be considered to be the most dangerous complication, inflammation of the parts within the chest.

In cases attended with great depression of the fractured bone, the necessary incision should be made in order to raise with an elevator the portions of the broken sternum, or to extract with forceps any loose portions, which seem to be strictly compressed. However, it is not often necessary to replace the sternum, unless to raise a depressed portion of still bone or to give vent to extravasated fluid. In the few of these circumstances, I believe, with Mr. C. Bell, the successful application of the trepan can never be easily necessary. Should the surgery may be called upon to extract large portions.—(See Operative Surgery, vol. 2, p. 628.) Such an operation, however, may sometimes be proper when abscesses form under the sternum or the bone is affected with necrosis, and the separation of the damaged parts is likely at any considerable time.

Functurae of the alveoli are more frequently produced by gun-shot violence than any other class, and in these cases, there are generally entire epididymis rupturing extrinsically. At the battle of Marston, the French general Chaucer received such a wound, with which he lived nearly a month: the injury was attended with no many epididymis, but when they were removed, the pulsation of the heart was visible to a considerable extent.—*Ipswich, vol. ii, p. 244.*

The scapulothoracic articulation, which consists of two synovial joints, is liable to fracture. Little injury, however, can be done to this joint, a case, thus releasing the subclavicular muscles by raising the thorax and pelvis, and then applying a piece of wet plaster and a roller over the part, for the purpose of keeping it steady. When the chest has been restored, the patient should always be laid.

FEATURES OF THE LINE

These generally happen near the greatest convexity of the base, several of which are often broken together. The first rib being protected by the diaphragm, and the inner ribs being very flexible, are less liable to be fractured than the middle ones.

When the spirit of a fractured rib is broken inward, it may lacerate the pleura, wound the lung, and excite the dangerous train of symptoms attendant on emphysema.—(See Emphysema.)

A pointed stenosis of the rib, projecting upwards, may also cause an inflammation of blood; or by its irritation produce inflammation in the vessel. A fracture which is not in all displaced is very difficult to detect, particularly in the scapula; and its weight is very frequently never discovered. The scapula should always be felt on the part where the patient seems to experience a prickling pain in the absence of inflammation, or where the violence has been applied. The patient should never be requested to cough, in which action the ribs must necessarily heave to a uniform motion, by which a fracture will often be rendered perceptible. All the best practitioners, however, and in the last resort adopting the same measure, when there is reason to suspect a rib to be fractured, as if there were usually known to be the case by the occurrence of a crepitation, or the progress of one end of the fracture; which, united, in the fractures which are displaced, makes the state of the accident sufficiently plain.

A broken rib is treated by dislocation either in the direction of the diaphragm of the breast, or in that of the pleura. The rib, being fixed positively in the centre, and uniformly in the strength, cannot become dislocated. Nor can one of the broken pieces become higher or lower than the other, because the same muscles are attached to both fragments, and keep them in an equal distance from the neighbouring ribs. The only possible dislocation is either upwards or downwards. However,

slange fractures of the ribs, due from urgent expiration, require very simple treatment. The girded object is to keep the broken bones as immovable as possible. For this purpose, after a piece of soap-planer has been applied to the side, and over a proper compress, a broad linen roller is to be firmly put round the chest, so as to exclude the action of the ribs, and compel the patient to perform respiration chiefly by the descent and elevation of the diaphragm. A secondary aim prevents the tendency from slaying downwards. When the fractured rib is depressed inward, the compresses should be placed on the anterior and posterior part of the bone. As a roller is not to become slack, many surgeons, with good reason, prefer a piece of strong iron, large enough to surround the chest, and lined with pack-thread, so as to compress fibres in the due degree.

When there is fracture, from the symptoms, to think the legs injured, as supposed to arthritis, excruciating and agonizing bleedings should be practiced. Indeed, as post-mortem is always liable to excruciating the patient, and as a most dangerous contraindication, every person free from debility, either having a broken rib, or supposed to have such, should always be bled: it is the first instance. The epistomized patient, with opium, is an excellent medicine for opening any cough, which may destroy the fracture, and give the patient infinite pain.

FACTORS OF THE RATIO

Although never superficial, than the other leaves of the genus, the spectrum is less irregularly fringed; a fact evidently, as Hoyer has remarked, by its thick-

ness, its springy texture, and the advantageous way in which it supports the weight and efforts of the whole trunk. For the reason to be broken, the violence must be very great, like that resulting from the fall of a very heavy body, or the passage of a carriage-wheel on the narrow sole of the bone, or a fall from a great height on that part. On the other hand, fractures of the scapula, when they do happen, are more common than those of the case is tonight, because, in addition to the first degree of contusion and laceration, with which they are connected with the latter ones are complicated, there is almost always great damage done to the neural nerves; a kind of injury which may have fatal consequences. Hence extension of time, inability to retain that fluid, necessary discharge of the bone, paralysis of the lower extremities, &c. Another personal danger also depends upon the injury which the pelvic viscera may have suffered from the same violence which broke the bone.

When the structure is situated at the upper part of the incision, which seldom happens on account of the thickness of the bone in that situation, there is no displacement, unless the bone is completely, and the fragments are driven inward by the same force which produced the fracture; a case which always requires great injury of the external and internal soft parts. As the whole fracture occupies the lower portion of the bone, where it is less thick, the inferior fragment will be displaced inward, towards the incision. And, as Boyer observes, *fractures of the upper part of the bone are not in general easily detected.*—(*Prat. de Med. Chir.* t. 3, p. 152.)

When the evidence has been such as to make it probable that it has extended its efforts to the police, viz., that they stand in the power of an evil and to be adopted for the prevention of infestation. In particular, as people living should be practiced, and, if necessary, repeated. Lessons should also be applied in the vicinity of the courts, and the para-legal cases with the local police courts. Any delay, either in the examination or prevention of the crime and loss, will also cause delay in the immediate and continued attention. (See *Review, Refutation of; Jurisdiction of, &c.*) With regard to the particular means for preventing the union of the structural members, speaking in the most important, and after the risk of infestation is over, all that can be done is to apply a piece of the employment, as it is to the poor, and put a collar around the neck, or a T. bandage.

FRACTURES OF THE C6 VERTEBRAL

Though much stiffer than the exoskeleton, it is less frequently broken, because less exposed to external force, and capable of a degree of movement, by which it eludes all effect of violence. But in *silvery* persons, in whom the different pieces of the os coracoclavicularis are connected by arthroclasis, a fall on the buttock may fracture the bone. The accident is known by the torbidity of the fragments, and the acule pain produced when the flaps are moved; the fragments being then distributed by the action of the gluteal muscles, some of whose fibres are attached to them. (Cramer, l. 2, p. 350.)

The treatment of fractures of the os coxae consists in exposing the fracture, establishing displacement or non-displacement, according to the particular state of the soft parts, and taking blood away from the patient, adopting the antiseptics, regimen, and retaining the patient in a recumbent position his back or sitting down. He should also avoid walking, so as to put the great muscles into action, which would disturb the broken bone. All formal attempts at reduction are not only useless in respect to the fracture, but highly injurious to the soft parts, which are not in a state to bear handling without ill effects.

FLATTENING OF THE ORAL TECHNIQUE.

The structure and shape of the oar (scapula), and the thickness of the soft parts by which they are covered, explain why they are less often fractured. When such accidents happen, they are generally produced by the pressure of heavy carriage-wheels over the pelvis, falls from great heights, the kick of a horse, &c., and are always attended with considerable contusion of the external soft parts, and sometimes with great injury of the pelvic vessels. The urine appears opaque, and the blood is sometimes broken off by the kick of a horse. (Roux.)

The two ossa innominata may be broken together; but commonly only one of them is thus injured. Most frequently the fracture takes place in the upper epipubic portion of the bone, known under the name of the *Alia*, though sometimes it happens either in the ischium or the os pubis. The violence of contusion may be limited to one part of the bone, or extend to several parts of it; and there may be a greater or less number of fragments, and these unconnected or not with displacement. In many instances, in which the pelvis has been violently shaken between two bodies, or run over by a heavy carriage, the bones of the pelvis, besides being fractured, are dislocated, some presenting examples of which would have been recently published.—(A. Cooper's *Surgical Remarks*, part 1, p. 256 &c.)

During my apprenticeship, at St. Bartholomew's Hospital, several cases occurred in which the os ilium, or ischium, or os pubis, were forced fractured on opening the bodies after death; and when the great violence necessary to produce the accident is considered, we cannot wonder that the injured parts of the pelvis should frequently prove fatal. Fractures of the ossa innominata are invariably attended with more or less contusion of the soft parts on the outside of the pelvis; and when the violence has been very great, the pelvis viewed may be seriously bruised, sprained, or lacerated, and the large nerves, contained in the pelvis, or the spinal marrow itself, injured: hence, extravasation of blood, or effusion in the cellular membrane of the pelvis; ecchymosis deeply seated even in the substance of the muscles or other organs; injury of the kidneys; complete loss of motion; a paralysis of the lower extremities; a discharge of blood or a black ichthyous matter by vomiting or stool, either immediately or at more or less distant periods from that of the accident; retention of urine; fever; painful tension of the abdomen, more or less inflammation of the peritoneum and bowels; the formation of abscesses, which are sometimes of great extent; sloughing; and death.—(Hager, *Trakt des Huf. Chir.* t. 2, p. 154.)

As the same article has observed, the violence necessary to fracture of the ossa innominata may produce a displacement of the fragments, and vary than from or less away from their natural situation. When the piece of os ilium is broken, the splinters may be propelled into the canal of the urethra, or even through the bladder, and give rise to extravasation of the urine; or by merely compressing these organs, they may cause more or less interruption of their functions. But unless the fragments be displaced by the same force which caused the fracture, they can hardly be drawn out of their place by any other circumstance; when they are retained by the splinters attached to both fragments, and by surrounding ligamentous expansions.

Owing to the deep situation of fractures of the pelvis, and to there being no displacement nor mobility of the fragments, the diagnosis is sometimes attended with great difficulty. A specimen of the accident may be mentioned, when the pelvis had suffered great violence, the patient experienced great agony, and all motion of the trunk and lower extremities is difficult and painful. Under these circumstances, if the fracture should be in the ischium, especially the lesser and front portion, as in the os pubis, the mobility of the fragments or even a crepitus may be distinguished in a thin subject, if when he is lying horizontally, with his thighs well legs bent, and his head and chest elevated, the projecting point of the os innominatum be taken hold of, and an attempt be made to move the fragments in opposite directions. In such instances, however, no certain is given by Hager, viz. not to mistake the crepitation of air in the lungs, when attending large extravasations of blood, for the grating of the fractured bone.

In cases in which the fracture affects a part of the os innominatum very deeply placed, and it is limited to a single point of the os pubis or the ischium, so that no detached movable fragment has been produced, the exact nature of the case is easily made out with certainty before the patient's death, and the dissection of the parts.

Fractures of the ossa innominata are cases accompanied with serious danger. When the fragments are displaced, and do not admit of being reduced again,

the disorder arising from this release may have fatal consequences. And, as Hager observes, even when such displacements do not exist, these fractures are not less to be apprehended on account of the injury which the spinal marrow and the nerves, vessels, muscles, and viscera within the pelvis are likely to have sustained. These complications, which are almost inseparable from the fracture, may prove indeed directly fatal, by destroy the patient at a period more or less remote from the time of the accident. One striking accident of this kind, which I saw about two years ago, with Mr. Pies, of Cologne, proved fatal in about half an hour. Sometimes, however, the fracture is not extensive, and the violence which produced it has not caused any very serious injury of the vessels and soft parts; yet examples of this kind are numerous.

In these last cases, which are the most simple, a cure of the fracture may be easily effected by means of rest; a position in which all the chief arteries attached to the pelvis are relaxed; constant application; and, a ruler, or T bandage.—(Hager, *Trakt des Huf. Chir.* t. 2, p. 154.) The great indication is to preserve the continuation of influence of the parts within the pelvis, and even of the peritoneum and adjacent viscera, by repose and supported mobility. Any complication respecting the extension of the area and floor might also receive immediate attention. When there is great contusion, and the bones are very badly broken, the pelvis cannot bear the weight of a band without suffering the most excruciating pain. In all first cases assistance is such circumstances, there is a particular case, passed a piece of strong gauze was under the pelvis, and, collecting the currents into one collected state in a pelvis suspended from the top of the bed. This enabled the patient to move around with very little efforts, so that a bed could need to be placed under him. It appears to me that a bed constructed on the principles recommended by the late Mr. James Esch, might be of infinite service in these cases, as well as in many others, particularly complicated fractures and paralytic affections from closed fractures.—(See *Observations on Fractures of the Lower Limbs*, to which is added an account of a contraindication to amputation, and comfort in the lower limb, by Sir J. Keir, M.D., &c.) Mr. Esch has also mentioned his mechanical apparatus with great success in the treatment of a bad scrofula, and indicated for the treatment of fractures, and other cases, in which it is an object of high importance to enable the patient to empty the bowels without changing his position.

Sometimes, notwithstanding the fragments adhere antipathetically to each other, abscesses continue to be produced from sitting on the pelvis; particularly when they are detached splinters driven inwards. These abscesses of matter should be opened as soon as a small fluctuation can be felt. The splinters may wound the rectum or bladder, and cause an extravasation of urine. I should extremely regret what had happened to effect from the bones of a normal case, as the discharge of the effused urine. In these cases, a catheter should be kept introduced, in order to prevent the urine from collecting in the bladder, and shortening its length by itself into the cavity of the abdomen.—(Cooper.) A very interesting case of fracture of the ossa innominata, attended with rupture of the bladder, and followed by a fatal peritonitis, has been recorded by Cooper.—(Narrative Journal de Médecine, Mars, 1819.) The ossa pubis were forced half an inch from each other. The horizontal branch of the pubis, and the ascending ramus of the ischium, were broken; the ureters dislocated from the ossa ilium, and extravasated within the cavity of the pelvis. The right sciatic artery aneurysm was broken only at its first part, and the blood still retained their momentum. A large quantity of blood was found extravasated in the bladder, and about the peritonea. As soon as the abdomen was opened, three pints of a yellowish fluid, looking a styptic fluid, immediately gushed out. In this case, catarrhes of various kind were extremely even a syphilis adapted to these was said, but nothing could be done except to let a little stream of blood. The possibility of mistaking a fracture of the innominata for a dislocation of the thigh-bone, and the difference of these cases as explained by Dr. A. Cooper, have been mentioned in the article on Scrofula.

FRACTURES OF THE THIGH.

The os femoris is liable to be broken at every point, from its condyles to its very head; but it is at the middle third of this extent that fractures mostly occur. The fracture is sometimes transverse, but more frequently oblique. The latter direction of the injury makes a serious difference in the difficulty of making the case without future deformity or lameness. Sometimes the fracture is comminuted, the bone being broken in many places; but one, and sometimes two, are associated with a wound, communicating with the fracture, and making it when it is termed compound. As Pott remarks, however, the thigh-bone is less seldom broken into several pieces than other bones more extensively studied.

A fracture thigh is attended with the following symptoms: a local acute pain at the instant of the accident; a sudden lameness; it is usually a limb; a preternatural mobility of one portion of the bone; sometimes a very distinct crepitus when the two ends of the fracture are moved against each other; deformity in regard to its length, thickness, and direction of the limb. The latter change, viz. the deformity, might be so accurately calculated; for, having a cerebral faculty to *feel*, especially in oblique fractures, our disfigurement at the treatment is in previous time. (Desault, *op. cit.*, t. 1, p. 181.)

Oblique fractures of the thigh are attended with deformity. When this is considered in relation to length, it appears that, in oblique fractures, the broken limb is always shorter than the opposite one; a circumstance arising from the ends of the fracture slide over each other. We may also easily convince ourselves, by examination, that the deformity is owing to the lower end of the fracture having ascended above the upper one, which remains stationary. What power, except the muscles, can communicate to the lower portion of the fractured bone, a motion from below upwards? As several attached to the pelvis and at the other to the part of the bone, the patella, the tibia, and fibula, they make the former assume their fixed point, and drawing upwards for leg, the knee, and the lower portion of the thigh, they raise directly or indirectly the displaced extremity. In producing this effect, theiceps, semitendinosus, semiperoneus, semitarsus, gracilis, sartorius, &c., are the chief agents.

For the purpose of enervating the power of the muscles to displace the ends of the fracture, attention is made, in Desault's works, by Bistot, of a carpenter who fell from a scaffold and broke his thigh. The limb, the next day, was as long as the other; but the man had a complete palsy of his lower extremities, and would not discharge his urine. The man was applied, the muscles were relaxed their power, and then the shortening of the limb began to make its appearance.

Besides the action of muscles, there is another cause of displacement. However firm the bed may be, but which the patient is laid, the bedclothes, more prevalent than the rest of the body, soon form a depression in the middle, and thence follows an inclination of the place on which the trunk lies, which, gliding down some downwards, pushes before it the upper end of the fracture, and makes it ride over the lower one. The muscles, irritated by the points of bone, become their contraction, and draw upwards the lower part of the bone; and from this double motion of the two ends of the fracture in opposite directions, there sliding over each other results.

Transverse fractures are less liable to be displaced in the least when, in position of the bone, because, when one is correct, the ends of the fracture being a natural resistance to each other, the lower ends, drawn upwards by the muscles, remain with assistance from the upper one, which being itself retained downwards by the weight of the trunk, pushes the former before it, and thus both retain their position in relation to each other.

The deformity of a fractured thigh, in the transverse direction, always communicates that which is lameness; but sometimes it arises from. This is the case, when, in a transverse fracture, the two ends of the bone lower their ends, one being external upwards, the other internal, or one remaining in place, while the other is separated. The upper end of the fracture is not now, as in the foregoing instance, motionless in regard to the movable action; the contraction of the

peroneus, psoas, iliacus internus, and upper part of the triceps, draws it from its natural direction, and communicates to it motion.

The deformity of the limb in regard to its direction, is either the consequence of the blow, which produced the fracture, or, what is more common, of the ill-directed treatment of persons who carry the patient. Thus we see that an injudicious posture bends the two portions, so as to make an angle.

Whatever may be the kind of deformity, the lower end of the fracture may retain the natural position in which it is placed, or, on the contrary, a rotatory motion to which it is liable, or, on the contrary, a rotatory motion to which it is liable, which is very common, is towards, which is more unusual. This position always aggravates the displaced state of the fracture, and should be attended to in its reduction. (Desault, *op. cit.*, t. 1, p. 180, 185.)

Every one, at all initiated in the surgical profession, knows that there are two very different methods of treating fractured thighs. In one, which was much resorted to and practised by Desault, and is still universally positioned in France, the limb is kept in the straight or extended position. In the other, the limb is laid upon its side, with the knee bent; a mode which was employed by the celebrated Mr. Pott, and since his time has found many partisans in this country. To these two positions for fractured thighs, we may now be added that in which the patient lies upon his back, with his thigh and leg in the least position, supported on two oblique planes, or surfaces, the open angle of which is towards the knee. This last position, however, has been more particularly recommended for fractures of the neck of the femur, though, if it be advantageous for them, I see no reason for not giving it a fair trial in other fractures of this bone.

That Mr. Pott did not of certain advantage of the straight position; that he was blind to the imperfections of his last position; and that he exaggerated the power, which we have, of withdrawing all the muscles of a limb by palsy; I am detecting suspicion of the present day will be inclined to deny.

Were we to weigh the privilege of thinking for ourselves, and especially to mould our opinions according to any authority, however high, we should either fall into very considerable errors. Were we to believe the blind faith or opinion passages in Mr. Pott's Remarks upon Fractures, we should suppose possible and practicable to relax at once, by a certain posture of the limb, every muscle associated with a fractured bone. If the first vol. of his works, page 283, vol. 1793, he observes, in speaking of what some best answer the purpose of insensibilizing the muscles from displacing the fracture: "Is it not obvious, that putting the limb into such position as still relax the whole set of muscles belonging to, or in connection with, the broken bone, must be superior such purpose?" And in the next page, "What is the reason why we must, however superficially acquainted with the art, ever think much trouble in setting a fractured os humeri? is it not because both practical and experienced in putting the arm into a state of flexion, that is, into such a state as relaxes all the muscles surrounding the broken bone?" Also, in page 285, he continues, "Change of posture must be the remedy, or rather, the placing the limb in such position as to relax all the muscles." This to have all the muscles relaxed in cases of fracture would be desirable, were it also practicable, every one will admit; but the possibility of accomplishing it, so long as different muscles have different uses, different attachments, and different sympathies to the bones, every one must grant to be only a visionary project. For instance, to sit the patient and support, in the case of fractured os humeri, extended to above, rather than in putting the fibres of the biceps and coracobrachialis into a state of tension, at the same moment that they relax the triceps and brachialis externus!

The position of the fractured os femoris, says Mr. Pott, should be on its outside, resting on the great trochanter; the patient's whole body should be inclined in the same side; the knee should be in a middle state between perfect flexion or extension, or midflexion; the leg and foot, lying on their outside also, should be well supported by pillows, and, should be rather higher in their level than the thigh; one very bold spirit of soul, halberd cut and well covered with wool, rat, or tow, should be placed under the thigh, from above the trochanter quite below the knee; and

spines, somewhat shorter, should extend from the groin below the knee on the inside, or rather in this position on the upper side. The bandage should be of the eighteen-fold kind, and when the knee has been set, and the thigh well placed on the pillow, it should rest, without necessity (which frequently in this method will seldom occur), to ever moved from a single, until the fracture is united; and this union will always be accomplished in less of less time, in proportion as the limb shall have been more or less disturbed. — (Part.)

Here only two spines are mentioned; the surfaces of the femoral diaphysis employ four. After placing the patient in a proper position, the necessary extension is to be made. Then the under spine, having upon it a broad foot, pad, and an eighteen-fold bandage, is to be laid under the thigh, from the great trochanter to the water study. The surgeon, before applying the soap plaster, laying down the tails of the bandage, and putting on the other three spines, is to take care that the fracture lies as evenly as possible.

In the position for a fractured thigh, Mr. Pott, we feel, directs the leg and foot to be rather higher in their level than the thigh; with what particular design, I have not myself been able to make out. Whoever hesitates upon the consequences of elevating the leg and foot above the level of the thigh, in the best position, will know that it is to twist the convulsion of the os femoris more outward than is natural. When a patient is placed according to Mr. Pott's direction, upon a common bed, the middle does sit in as much less the leg becomes situated very considerably higher than the thigh, and I am disposed to think that this is one cause why so many broken thighs are cured in so deformed a manner, that the foot remains permanently dislocated outwardly. The great propensity of the troops and other muscles to produce this effect, may also serve to explain the frequency of the deformity. It is not merely the depression of the middle of the bed which is disadvantageous: as the weight of the patient's body falls more upon one side of the bed than the other, in the best position of the limb, unless the sitting is tight and the mattress very firm, it happens that such a deformity is formed as to render it exceedingly difficult, if not impossible, to make the patient continue daily upon his side. It cannot be expected too forcibly, that fractured thighs should always be laid upon beds and pillows to sink much. When this happens, no rational dependence can be put in the efficacy of the best position, and, as Desault has explained, the better thing is hurried also in the struggle posture.

The most enthusiastic advocates for the best position, must allow, that it leaves the leg and foot too movable and unsupported, and that, though it may relax the muscles, which have the most power to destroy the resistance of a fractured thigh, it yet leaves a want of muscle sustained, quite sufficient to destroy the cure of the bone. Hence, practitioners should endeavor to improve the apparatus employed, so that it may make a permanent resistance to the action of the muscles, and in the straight position such resistance may certainly be produced with great effect and convenience.

The weakness of Mr. Pott's observations on fractures would lead me to suppose, that had the moment a wound is partially closed, it becomes incapable of sitting on or distending a fracture. Now if this were correct (which it cannot be), we should not have the power of completely healing an extending war wound; but as soon as the set of muscles designed for this purpose were partly relaxed by the distention or half-extension of the joint, they would be deprived of all further power. Therefore, in addition to the arguments to be brought against the best posture, arising from its not actually relaxing all the muscles connected with the broken bone, we are also to take into the account the fact, that the partial relaxation of any muscle by no means incapacitates it from acting.

In the earlier editions of the Dictionary, I expressed a preference to Mr. Pott's method of treating broken thighs. Now entire reflection, however, and subsequent experience have made me a convert to the recommendation of Desault on this subject. The terrible compound fractured thigh, which I had under my care in the carriage in Holland in the year 1715, could not have been at all relieved by any apparatus yet merely upon the thigh itself. The extremity of long spines, situated the whole length of the trunk, was in those cases particularly necessary. With such spines, which

surround steadily the fracture itself, the knee, leg, ankle and foot, year passed that, in fact, even be removed upon an emergency from one place to another, without any considerable disturbance of the broken part. The few spines to be done in the best position, with short spines, merely applied to the thigh, suffering no sleep to the leg, and not containing the surfaces of the broken bone.

There are some excellent remarks on the treatment of fractured thighs in the writings of Desault. It is observed, that, if we compare the natural powers of displacement with the artificial resistance of almost every apparatus, we shall find that the supposing between such forces is too great to let the bones go to the latter. The action of the muscular power, which is always at first very strong, may afterwards be gradually diminished by the extension exerted on them. A power incessantly operating can effect what another greater power, temporarily applied, cannot so soon accomplish, and the compression of several bandages tends also to lessen the force of the muscles.

Desault entered in the History of the treatment of fractured thighs, without any kind of deformity. This system, it is said, was owing particularly to the well-contrived employment of extension and compression of the muscles. The advantage of making the muscles a long while extended, in order to diminish their power, is especially evident in the reduction of certain dislocations, as those of the shoulder, in which we often cannot succeed till the muscles have been kept on the stretch for a greater or less time. The fracture of the patella and olecranon equally demand the utility of compression for the same reason; as when the muscles are not steadily compressed by the bandage, they draw upwards the fragments of bone with double or triple force.

To the reduction of fractured thighs in the best position, Desault entertained the following opinions: the difficulty of making the extension and counter-extension, when the limb is so placed; the necessity of that as playing them in the fractured bone itself, instead of a situation remote from the fracture, as, for example, the lower part of the leg; the impossibility of comparing with precision the broken thigh with the sound one in order to judge of the regularity of the shape; the disadvantages of this positioning contrast, though fully diffused, with most naturally the bones, vessels and parts of a part of the trunk on the great trochanter of the affected side; the impossibility to which the limb is exposed when the patient lies in motion; the difficulty of fixing the leg firmly enough to prevent the effort of its motion on the thigh-bone; the necessity of adopting this method, when both thighs are fractured; lastly, experience in France having been little in favour of such posture.

Also, what is gained by the relaxation of some tendons, is lost by the tension of others. The such persons (nearly always men), Desault considered the best position, and always employed the straight one, which was advised by Hippocrates.

But, Hennen, and Duvetney considered the straight position to be applied just above the condyles of the os femoris. Duvetney remarked that this position rendered it necessary to employ very great force, and he preferred extension over the foot. Hennen also was considerable the inconvenience of the partial pressure made on the muscles, which, increasing and relaxing them to and fro, multiplies the chances of the union of the fracture. For nearly similar reasons Desault exposed their defects, introduced it in the History, and the success which he experienced from this practice contributed materially to its more general adoption.

Desault, as we have stated, preferred the straight posture, and laid his patients on surfaces and beds in work with the weight of the body. The latter policy, formerly in common use at the Hôtel-Dieu, had this inconvenience. For those, in cases of fractures, Desault substituted a firm, curvilinear band, which did not allow the continual change of position to occur which a soft bed does. The object of every apparatus being to keep the ends of the fracture from being displaced, the mechanism of every contrivance for this purpose should be directed against the causes of the displacement. These are, 1, the action of the muscles drawing upwards the lower end of the fracture; 2, the weight of the trunk propelling downwards the upper

end. Hence, every apparatus invented to prevent displacement of a thigh fractured obliquely, should, 1. draw and keep downwards the lower end of the fracture; 2. vary and maintain upwards the upper end of the fracture, and the trunk which is above it. This principle is of general application, and only subject to a few exceptions in transverse fractures, attended merely with displacement in the direction of the diameter of the limb, or none at all. 3. There must also be the apparatus to preserve to the position of the lower portion of the broken bone, so as to keep the limb steady, even in case of any sudden motion.

If we compare the operation of the different pieces of our apparatus with the above indications, Desault says, we shall find that without permanent extension they are not very efficient. With regard to bandages, whether a roller or eighteen-tailed bandage be used, they all have one common mode of operating; they press the muscles towards the ends of the fracture, so as to make them form a kind of internal case for the fracture, and thus they make lateral resistance against the parts. In this matter, bandages essentially fail in preventing displacement sideways, and are particularly ineffectual in transverse fractures. But what is there, to hinder the two united surfaces of an oblique fracture from slipping one over the other? When power is there to keep the limb from receiving the effects of accidents which? Is the pelvis kept back? Is the action of the muscles resisted? The latter is indeed somewhat diminished by the pressure, and this is the chief use of the bandage; but, with such compression, is enough to prevent the longitudinal displacement of the broken bone, especially if the bandage be applied strictly as we have said.

These remarks apply also to compresses, *petits moyens* create une grande cause.

Spitals are useful in firmly fixing the limb, and guarding it from the effects of accidental shocks, or of contusions of the splinters. They operate more powerfully than bandages, in preventing lateral displacement; and hence they suffice for transverse fractures, without permanent extension. They also resist the motion of the thigh towards the knee. But when the knee itself constantly is oblique, will they hinder the ends of the bone from sliding over each other, and the consequent shortening of the limb? They obviously could only be so by the friction of the different pieces of the apparatus, especially the tapes, which serve it; and then, to render the resistance efficient, they must be tied so tightly as to create danger of mortification. Will the splints prevent the trunk from descending, and protruding before it the upper end of the fracture? Will they hinder the action of the muscles on the lower end? Will they, in short, fulfil all the above indications? Their chief use is to prevent lateral displacement, and keep the limb steady. Hence, they should extend along the leg as well as the thigh, which is what I have observed whenever the lower part of the limb is affected by force.

The main service principally to keep the limb from being pulled by the splints, and their action in preventing displacement of the fracture must be not trivial.

According to Desault, the ordinary pieces of apparatus, when, as we examine any permanent extension, may suffice for transverse fractures; but they are always insufficient when the fracture is oblique, because they do not fulfil the essential indication of drawing downwards the lower end of the fracture, and keeping the other end steady.

He intended that the object principally to be aimed at was with a suspension, that the foot, leg, thigh, and pelvis should be suspended one above the other, so that, though the different parts thereof might be drawn in different directions, yet they would sit, with respect to one another, preserve the same natural relation. He intended the following apparatus to answer these purposes.

A strong solid, long enough to extend from the roots of the os ischii to a certain length beyond the sole of the foot, and rather more than two inches and a half broad, with such an os extension as to form the form of a pelvis, and terminating in a rectangular table, is a principal part of Desault's apparatus. It is applied to the external side of the thigh, by means of two strong linen straps, each fixed to a pin on the

The middle part of one table is to be raised to the middle of the thigh, so as to support (that) as ends are

brought to the smaller side of the thigh, passed through the middle, and knotted on the anterior side. Bands are to be previously placed under the middle part, in order to prevent any dangerous pressure; as well as on the tuberosity of the ischium, which Desault considered as the principal point of action of this band. The inferior part of the leg is next covered with pads, so that the middle part of the second roller is placed, the extremities of which cross on the inner and upper part of the foot, then on the sole, after which they are covered outwardly, and are each passed through the middle, and knotted with one other on the right, with such a degree of force as to put the inferior portion of the femur downwards, and push the splint upwards, and, by this means, the pelvis and superior portion of the fractured bone. On the internal side of the limb is placed a second splint, which extends from the superior part of the thigh to a certain distance beyond the foot. A third is placed on the anterior part of the limb from the ankle to the knee. The superior extremities of the anterior and exterior splints are fixed by means of a bandage passed round the pelvis. A roller, the middle part of which is placed under the sole of the foot, and the extremities crossed on its superior surface, and fastened to the splints, operates with them in preventing the foot from moving.

Before applying the apparatus, Desault covered the whole limb with compresses, wet with a solution of the acetate of lead. Over these Desault's bandage was put, and a roller round the foot, all wet with the same lotion. For more particulars the reader is referred to the *Parvum Chirurgicum*, vol. 1. *Quæstio* Chir. de Desault, per Boerhaave, J. L. Boerhaave, *Methodus* de Fractura, in *opere* Medico-chirurgico all' Apparatto di Desault, &c. Palermo, 1814. *Boerhaave*, *Trattato della Fractura*, &c. 2. 3. *Ridderstedt*, *Novæ*, Chir. 1. 3. and 4. Boerhaave's apparatus for fractured thighs is described in the last edition of the *First Lines of the Practice of Surgery*.

Instead of the position advised by Desault, we have recommended by Desault and Boerhaave, Dr. C. Hall prefers the posture in which the patient lies upon his back, with the limb supported in the best position by means of a wooden frame. This machine is simple enough, consisting of boards ten or eleven inches in breadth, six inches from the heel to the knee, the other from the knee to the inferiority of the ischium. Upon the knee of it they are united at its angle, where a horizontal board connects their lower ends together. Thus they form two sloping surfaces, to which distally they slant, and lower which the limb can be placed in an easy bent position. Near the edge of the inclined boards, holes are made perforated with pins. After the foot has been set, a line splint is applied, from the hip to the sole of the knee, and another along the inside of the thigh. See *Operative Surgery*, vol. 1. p. 103. I consider a very tolerable substitute of this mode of placing inclined splints. However, the foregoing apparatus does not sufficiently secure the leg and foot from motion, though, with the aid of a roller and a foot board, this advantage might easily be obtained. The fracture-splints, devised by me from Mr. Hall, is essentially calculated for five modes of treatment, with some additional recommendations, that the obliquity of the two surfaces on which the limb reposes can be altered at occasion most proper;—there is a foot-board for the support of the foot, and a contrivance by which the patient is enabled to have access without moving himself or changing his posture in the slightest degree. (See his *Practical Observations in Surgery*, p. 115, &c. New-Land, 1825.)

Fractures of the Neck of the Thigh Bone.

As this is a subject which has of late years excited considerable discussion, the reader cannot be too particular in ascertaining that three distinct kinds of fracture, very different in their nature, treatment, and result have been generally confounded together under the name of a fracture of the neck of the thighbone; for much of the dispute that has prevailed, whether these fractures will unite like those of other bones, seems to have proceeded from this false opinion of fracture not having been properly distinguished. Two of the kinds will by means of nature, lose their fractures; but the other, as it usually occurs, is attended by some exposure not so distant of a similar case of union; or, at all events, they declare that the cure has

and, as Camper has remarked, it is mostly only an effect of the force of the muscles, the line of gravity of the body as, by contraction of another, inclined backwards; the tendons at first contract to bring it forwards again, the tendons act on the patella; the breaks and the fall ensues. That it is the effect of the action and not the fall which merely breaks the tibia, is well ascertained. Sometimes the fracture occurs, though the patient completely succeeds in preventing himself from falling backwards, as we first experienced in two cases reported by Sir A. Cooper. (*Surgical Essays*, part 2, p. 351.) A soldier broke his patella in endeavouring to kick his opponent; the operation has been broken in throwing a stone. In the operating theatre of the Hôtel Dieu, both the knee-joint of a patient were broken by the violent spasms of the muscles, which followed an operation for the bone. The force of the muscles occasionally ruptures the external tendon of the anterior muscles, or, what is more frequent, the ligament of the patella. Of these cases, Pott, Blandin, and Sabatier met with examples. When the patella is broken lengthily, the case is always outwardly valuable. (*Illustra. Chir. de Desault*, t. 1, p. 283.)

A transverse fracture of the patella may also originate from a blow or fall on the patella; but in common cases it is produced by the violent action of the extensor muscles of the leg. It is only of late years, however, that the true mode in which the bone is usually broken has been ascertained. As Boyer observes, for the production of a transverse fracture of the bone, the extensor muscles of the leg need not act with a convulsive force, their ordinary action being strong enough to produce the effect; in question which the body is inclined backwards, and the patient is in danger of falling upon his occiput. In this state, the thigh being bent, the extensor tendons of the leg give their powerful, in order to bring the body forward and prevent the fall backwards; and the patella, whose posterior surface thus rests only by a point against the knee part of the condyles of the femur, is placed between the resistance of the ligament binding it to the skin, and the action of the extensor muscles. A fracture now happens the more easily, because, by the tension of the knee, the line of the extensor muscles and that of the ligament of the patella are rendered oblique, with respect to the vertical axis of the bone, which is bent backwards at the point where it rests upon the condyles. (*Traité des Mal. Chir.* t. 2, p. 322. *C. Bell's Operative Surgery*, vol. 2, p. 255, *Ann. Lond.* 1809. *A. Cooper's Surgical Essays*, part 2, p. 283.) By violent spasmodic action of the extensor muscles, however, the patella may be broken conversely, which the limb is possibly straight. A very singular case is mentioned by Sir A. Cooper, where a patella, which had been formerly broken and mended by ligature, was again divided into two portions, in consequence of the destruction of the mending medium by absorption. (*Phil. Mag.* p. 1805.) A case is also on record, where the ligamentous stuffing introduced was so incorporated with the skin, that when the latter happened to be incised, the knee-joint was laid open, and suppuration became necessary. (*Ed. Ann. of Surgery*, vol. 2, p. 231.)

In transverse fractures, there is a considerable separation between the two fragments of the bone, very perceptible to the finger when the hand is placed on the knee. The separation is not accompanied equally by both portions; the upper one, elevated by the extensor tendons, is drawn upwards very forcibly by these powers, which the patella no longer resists; while the inferior portion, being firmly connected with the ligament below, is not moved by any force, and can only be displaced by the tension of the leg to which it is attached. Hence the separation is least when the limb is extended, being then only produced by the upper fragment; greater when the thigh is bent, because both powers contribute to it; and it may be increased or diminished by bending the knee more or less.

As Boyer has particularly noticed, the deviation of one of the fragments exposes the end of the patella, making a material difference in these cases, because it is a part of great importance in the cure. According to this author, a portion of it is simple because of the patella generally causes laceration, and the separation of the fragments is thus not very considerable; but

violent action of the extensor muscles, the fall subsequent to the fracture or bending of the knee too much, may separate two pieces of bone far from each other, and rupture the ligaments expressively. (*Traité des Mal. Chir.* t. 2, p. 283.) According to Sir A. Cooper, "when the ligament is benighted, the separation will be at half an inch; but under great extension of the knee, the bone is drawn six inches upwards, the capsular ligament and tendons of the muscles covering it being then greatly lacerated." (*Surgical Essays*, part 2, p. 351.)

The upper portion of bone may be moved transverse, and pain is thus excited, but no erysipelas can be felt, as the two pieces of bone are not sufficiently near each other. When the swelling of the knee, consequent to fracture of the patella, is very great, the symptoms of the injury may be some or less obscure. However, in consequence of the mobility of the extensor tendons to move the leg, except in a few cases where the fracture is very low, the patient cannot stand without difficulty, and is unable to walk.

In the treatment, the chief indications are to overcome the action of the extensor muscles of the leg, and to keep the fragments as near each other as possible, partly by a judicious position of the limb, and partly by mechanical means. The first indication is fulfilled by raising the above-mentioned position; 2d, by extending the leg. 3d, by bending the thigh on the pelvis, or, in other words, raising the femur, so that the distance between the knee and anterior superior iliac spine of the femur may be as little as possible; which object, however, will not regulate the body to be raised, and the person somewhat inclined forwards. At first, as the knee is not so adjusted, the patient should be placed in a sitting posture, the trunk leaning a right angle with the thigh. (*Ed. Ann.* t. 2, p. 316, *Illustra. Chir.* 1793.) 3dly, The tendons are to be compressed with a roller. The second indication, or that of placing and moving the fragments in contact, or as nearly as circumstances will allow, is a great measure already answered by the above-recommended position of the limb and thigh; but it is not perfectly fulfilled, since the upper portion of the bone is also pressed towards the lower fragment, and mechanically held in this situation by the pressure of an apparatus of bandage. And, in pushing the upper fragment towards the lower one, the surgeon should always be careful that the skin be not displaced and pinched between them.

Having described the principles which ought to be observed, I do not know that any great ability would result from a detail of the various methods of treating a broken patella, preferred by different surgeons. In the last edition of *the First Lectures of Surgery* may be found a description of the plan and apparatus employed by James Boyer. Desault's practice, which was related in the third edition of the Dictionary, I now deem as not being exactly such as modern surgeons would wish; not more any of his principles being erroneous, but because his apparatus is more complicated than necessary.

After putting the patient to bed upon a mattress, and in the desirable posture, with the limb confined, supported, and raised, as above directed, upon a well padded hollow splint, Sir A. Cooper applies at first no bandage to the knee, but covers it with linen wet with a lotion composed of the spirits of rose, tinct. 3v and water, viz. 7j. If on the succeeding day or two, there be much tension or erythema, leeches should be applied, and the dress continued; but the employment of a leech is not to be continued until the tension has subsided; for Sir A. Cooper asserts to that he has seen the greatest swelling, and such swelling as threatened gangrene, produced in these cases by the too early use of a roller. Instead of a circular bandage, placed above and below, the bandages, he said, drawn together with tape, &c., so as to bring the upper fragment downwards the lower one, thus exposed the suppurative process the following method. A leather strap is buckled round the thigh, above the broken and elevated portion of bone, and fixed this circular piece of leather another strap passes under the middle of the foot, the leg being extended, and the foot considerably raised. This strap is brought up to each side of the patella, and included in the leather band already applied to the lower part of the thigh. It may also be fastened to the skin at any part of the leg with tapes. The Ka. is

to be confined in this position five weeks if the patient be an adult, and six if advanced in years. Then a slight passive motion is to be begun, and to be partly insisted from day to day, until the flexion of the knee is complete.—(*Surgical Essays*, part 2, p. 91.) But, although the propriety of making any constriction of the knee with a bandage, when the skin is excited and inflamed, must be obvious, the surgeon might be supposed that such swelling and inflammation could not be avoided the best way is to place the limb in the right position, and pressing the upper fragment towards the lower one. Malmström ascribes the same error to many as frequent after this fracture, partly to the custom of not flexing or straightening the joint at once together with the swelling and redness, and partly to the fashion of bandaging the joint too tight, with a view of preventing its motion. But, says he, nothing can be clearer than that it is most advantageous to attend to the nature of the fracture first, and to the facility of the joint afterwards.—(*Recherches*, t. 2, p. 285, [1832.] Bone has likewise remarked, that the healing substance is apt to yield, and become loosened, by bending the limb too early, and he therefore never allows this motion to be performed before the end of two months. When the transverse substance is long, and the patient very slow in acquiring the use of the extremity, however, no should sit every day on a table, and endeavor to bring them into action, and as this increases, a weight may be added to the foot, as Hunter, Shelden, &c. recommend.

Nothing keeps the leg more firmly supported than a long, broad, even-sided splint, with a suitable pad, applied to the posterior part of the thigh and leg, and fixed there with a roller, while the limb itself is to be bent by raising the whole limb, from the foot to the top of the thigh, with pulleys, with, of course, great care a gradual ascent from the inferiority of the fracture to the foot.

The broken patella is seldom always united by means of a ligamentous substance, instead of bone.

Hunter, that an osseous union may follow a transverse fracture of the patella, and still more frequently a purpus is also one, but that in which there is not now the slightest doubt. Thus, I observed four patients in an unequalled specimen of a transverse fracture, united by bone, with the history of the case, and the appearance after the death of the patient from some other affection.—(*Boyer, Traité des Mal. Chir.*, t. 2, p. 255, &c.) In the collection of Dr. Williams Hagner, there is one well-marked instance of the bony union of a transverse fracture of the patella, and other examples have been seen in the last subject by Mr. Wilson.—(*On the Structure, Physiology, &c. of the Skeleton*, p. 248.) In Mr. Charles Bell's museum may also be seen similar specimens.—(*On Anatomy of the Spine and Thigh-bone*, p. 57, 58.) The reason why transverse fractures of the patella do not commonly unite by callus, is not owing to the want of power in this bone to produce an osseous connecting substance; for, as Lorry has several times noticed, if the fragments are kept in perfect contact by means of a suitable apparatus, their bony union becomes so complete, that scarcely any vestige of the injury can afterward be traced.—(*Journ. Chirurgical*, t. 8, p. 114.) Indeed, it is a fact, on which Lorry dwells as affording a proof that callus is produced, not by the pressure, but by the weight of the bones themselves. And what must add strength to the purport of the foregoing remarks is the consideration, that physiochemical or imputed fractures of the patella, which are not liable to any displacement from the action of the extraneous muscles of the leg, readily unite by bony union.—(*Histories of the Structure and Physiology*, &c. of the Skeleton, p. 325.) These a statement which, I think, could not be rendered doubtful by any experiments made on animals, without the advantages of epistaxis and proper treatment. Yes, there are other facts related, which prove that, both in longitudinal and transverse fractures, a ligamentous union is generally produced, when the fragments are separated; but if these are not drawn asunder, no osseous union takes place. Thus, in one case reported by Mr. A. Cooper, one-third of the patella was separated from the rest of this bone, and laid asunder by ligatures, a free motion being left between the fragments.—(*Surgical Essays*, part 2, p. 94.) The same gentleman dividing the patella longitudinally in a dog, without extending the division into the tendon above, or the

ligament below, so that the fragments could not be separated. In three weeks a close bony union was the result.—(*J. 50*.) A case is also related, in which a professor fractured the patella transversely, and the lower portion likewise perpendicularly. The transverse fracture united as usual by ligament; the perpendicularly one to bone.—(*J. 50*.) Mr. Charles Bell gives another explanation of the cause of union being by bone or ligament. In the common case, says he, if fracture of the patella by the sudden action of the knee (knee extension), the pieces are separated without the degree of violence which is necessary to produce division by bone. But when the patella is broken by a blow or kick, there is not only long extension, but also injury, mostly effusion, excoriation, and injury of the parts remote from which the violence has been applied, and the fragments are by force.—(*On the Structure of the Spine*, &c. p. 285.)

Theophrastus became formerly extremely respecting the transference of an elevation and protrusion of the collar into the joint after a fracture of the patella, and especially when the fragments are kept in contact, were long ascribed by Pott and Mead.—(*Pract. Chir. Works*, vol. 1, p. 252, ed. of 1788. And Don's Essay on the Fractures of the Patella, &c. 2nd. Lond. 1789.) On the contrary, as Mr. A. Cooper particularly remarks, "the internal articular surface of the bone preserves its natural smoothness."—(*Pract. Chir.*, &c.) How much doctrine of a separation of the articular surfaces with the difficulty of extension must have ever possible, appears difficult of explanation.

Pott, and some others, thought that there must necessarily an interference afterward, but from the two pieces of the patella, with a certain length of the connecting substance, might be advantageous in the nature of the union. But Boerhaave, Boyer, Mr. A. Cooper, Mr. J. Ellis, and others, have always stated that the greater the distance between the two pieces of the bone, the greater the difficulty afterward in making up a union of it with an equal good result.

In the treatment of a longitudinal or perpendicular fracture of the patella, the leg should be kept extended, without swell, and a cold lotion applied. After a few days a splint is to be put round the limb, and then a bandage with strong buckles, passing the limb above and below the patella.—(*A. Cooper*, vol. 2, p. 183.) Theophrastus of Hippocrates explains the fact, that a longitudinal fracture of the patella is soon firmly united.—(*Antiquary Med. Chir. de Paris*, p. 94, the *Journal*, 1820.) Consistent fractures of the patella are especially common in the death of the patient, unless perhaps he dies early. The injury, however, is not invariably fatal, owing to the loss of life in kind. I saw a case in St. Bartholomew's Hospital, in the year 1820, under Mr. Vissers, where the patella was broken to pieces, and the opening so extensive that the finger readily passed into the joint; yet, after a tedious suppuration, the formation of abscesses, and the removal of several fragments of bone, the patient recovered with a stiff joint. In general, however, I believe, with Mr. A. Cooper, that in compound fractures of the patella if the laceration be extensive, or the distention very considerable, amputation will be required; but if the wound be small, the patient not irritable, and no suppuration of the instruments or ligamentous tissue, it will be best to try to save the limb.—(*Vol. 2*, p. 28.) The wound should be dressed as usually in position, and advantage taken of coagulating eschar, perfect rest in a desirable position, a very low temperature, respiration, and gentle cooling medicine. Some writers the above remarks I have with another case of bad compound fracture of the patella in St. Bartholomew's Hospital, where it has been about a month. No fragments of bone have yet been removed, but a good deal of matter issues daily from the wound. The case must be regarded as a very promising one, though if bony union should not follow the joint will not, the limb will probably be saved.

Lond. 1789. Boyer in *Chir. Chém.*, t. 1, p. 14. T. Adams in *Trans. of the Associated Apothecaries*, &c. vol. 1.

FRACTURES OF THE LEG.

May be transverse or oblique. The first case is of

leged to be most common in children. Experience shows that the two bones of the leg are usually fractured together rather than single; a fact ascribed by Boyer to the strength of the knee and ankle-joints. — (*Threats to the Life*, Chap. 2, § 2, p. 202.) The direction of oblique fractures of the tibia is stated to be pretty constantly from below upwards, and from within outwards, the end of the upper fragment usually protruding itself under the skin at the inner and lower part of the leg. In these cases, the longitudinal displacement of the fracture is less common than the transversal and oblique. However, when it does happen, the inferior fragments are driven upwards and forwards, while the superior ones protrude externally and backwards. The angular displacement may be produced indirectly, the action of the superior muscles of the leg, or the weight of the distal end is bent upon the axis, projects backwards. But injury is almost invariably, if the bone is too much raised. A rotary displacement, most commonly by pressure in the direction outwards, is produced by the motion of the foot, and if this be raised too much upwards, the rotary displacement will be in that direction. A longitudinal displacement cannot take place in transverse fractures, on account of the complete union of the surfaces of bone; but in oblique fractures, the inferior fragments are almost always driven upwards by the action of the posterior muscles of the leg, in which position of the parts the lower ends of the superior fragments project forwards, and may be felt by the hand. Sometimes, however, when the motion of continuity is upwards downwards and outwards, the inferior portion will be produced by the lower pieces. In both kinds of displacements, the pointed ends of the pieces will bear and penetrate the integuments, and cause a compound fracture.

The usual symptoms denoting a fracture of both bones of the leg are, a change in the direction and shape of the limb, pain, and impossibility of walking, or bearing upon the limb, swelling of the fractured pieces, and a distinct crepitus.

Fractures near the knee are not very subject to displacement, on account of the thickness of the tibia in that part; but they are more dangerous than those of the middle of the bone, because often followed by inflammation of the knee-joint. Fractures close to the ankle are still more dangerous. Oblique fractures are very difficult to maintain, and when their displacement is upwards and forwards, the integuments are in danger of being torn by the protruding points of the superior portion of the tibia. — (*Nagel*.) It had been supposed that the leg most of the observations are applicable already defined on compound fractures is general.

When the site of the tibia is compared with that of the fibula, and the same symptoms of these bones to each other is remembered, an opinion might be formed, that the first could serve to break without the second. Experience, however, proves the contrary. And reasons for this fact, as Boyer remarks, may be deduced from the consideration that the tibia is the bone which supports the weight of the body, and that it is situated at the fore part of the limb, simply covered by the skin and flesh exposed to the effects of violence. — (*Threats to the Life*, Chap. 2, § 2, p. 203.) When the tibia alone is broken, the fracture is said to be generally transverse.

If the injury happens near the knee, the great extent of the frontal surface prevents any considerable displacement of the fragments; and the fibula, acting as a support to the external side, contributes also to this effect. But, however, has been one instance in which the tibia was broken by the kick of a horse, and the fragments, driven in the direction of the axis of the bone, when displacement could not be resisted, so that the bone remained protruding at the part.

The absence of displacement often renders the diagnosis of fracture of the tibia very difficult, and the difficulty is further increased by the little pain and inflammation produced by such a fracture, with which persons have been known even to walk.

Whenever there is reason to suspect the accident, in consequence of a blow or a fall on the leg, the part should be carefully examined. The fingers are to be moved along the anterior side of the tibia, the slightest irregularity in which may be easily perceived, on account of the being covered only by the skin; and the motion of the joint may be distinguished by grasping the opposite ends of the bone, and pulling them in vari-

ous directions. However, this motion and the steps are not always very plain, on account of the fibula not allowing the fractured portions to be sufficiently moved in one position.

In a review of the position and strength of the two bones of the leg, it will appear that the tibia supports above the whole weight of the body, every shock directed in the axis of the limb, and every kind of force applied also in the transverse direction, without operating upon any particular point. Hence the frequency of fractures of the tibia; and if the fibula is general, broken at the same time, the latter injury is less extensive to the tibia, and takes place lower. This structure is not capable of bearing the weight of the body, the impulse of external violence, and even the action of the muscles, after the tibia has given way. — (*Deputen*, *Annuaire Med. Chir. des Hôpitaux de Paris*, p. 15, 4to Paris, 1815.) On the other hand, as the same distinguished surgeon remarks, the fibula being principally designed as a support for the inside of the leg, it is particularly when the tibia is to be extended, and its lower end has to make resistance to all sorts made by that direction, that it is fractured; and if the lower part of the tibia be also sometimes broken by the same force, it is almost always comminuted, and not by the effect of a direct and instantaneous action upon the two bones. — (*P. 17*.) All fractures of the fibula, however, are not caused in the preceding manner; and Deputen concurs with Boyer, Mr. C. Bell, and all the best writers on this subject, in dividing these cases into two kinds: first, those in which the force is applied directly to the bone itself, secondly, the more important and serious cases, in which the force operates upon the fibula, through the medium of the foot. With respect to the first class of cases, the situation of the fibula on the outer side of the leg, a situation which would seem to expose it much to external violence; its slenderness; the advantage left between it and the tibia at the middle part of the leg; and the way in which each end of it runs upon the lower bone; would lead one to expect that its middle portion must often be broken; yet the case is less frequent than might be supposed. And, as Deputen observes, there are two reasons for this fact; viz. the protection which the fibula receives from the peroneus muscles, and the rarity of protrusion capable of producing a fracture by a direct cause. These fractures, which are not usually attended with difficulty, and in some cases even do not hinder the patient from leaning upon the foot, caused for the most part to be mortified, unless attention be paid to the manner in which the accident was produced, and to the presence of ecchymosis, and of some or less pain in the part which has been struck, or pressed upon; together with a degree of irregularity of the limb, perceptible by the finger, and a more or less distinct swelling and crepitus of the ends of the bone.

The usual causes of this sort of fracture are blows on the fibula, gun-shot wounds, the fall of heavy bodies on the outside of the leg, or the pressure of them over the same part. The fact is generally twofold, either upwards or outwards; and is most instances the accident is easily cured by means of rest, without being accompanied by any of the symptoms so often complicating other fractures of the fibula, produced by extension of the foot. — (*Nagel*, *op. cit.* p. 181.) A similar analogy may be remarked between fractures of the external part of the fibula and those of the corresponding portion of the tibia, and thus in respect to nature, symptoms, treatment, and consequences. Fractures of the middle of the tibia like those of the body of the fibula, are always accompanied by blows or falls on the fractured part, or by violence applied directly to the bone. Such fractures are scarcely ever attended with any difficulty in the limb, incapacity of moving it, or displacement of the fragments; and just as some individuals are able to walk with a broken fibula, others, notwithstanding a fracture of the tibia, are found capable of using their limbs nearly as well as if a severe blow from injury. The latter case, like that of a fracture of the fibula, can only be ascribed to the resolution of the bone in which the hurt was received, the pain, ecchymosis, irregularity, motion, and crepitus, which last effects are also not very obvious so high up the bone. Like fractures of the body of the fibula, those of the body of the tibia only require rest and the usual applications, and very seldom the bandage, as the

nary is the treatment of fractures of both bones of the forearm, or of those of the radius alone.—(Vol. vii. p. 58.)

Fractures of the shafts from an external cause may happen from the foot being violently thrust either inwards or outwards. In both instances the cause of the fracture is a change in the direction of the line in which the weight of the body is transmitted. In the first case, the axis of the tibia, and falling upon the astragalus, crosses the lower end of the tibia and the suppling, obliquely from within outwards, and after passing across the malleolus externus, extends to the outside of the os calcis. The parts then supporting the weight of the body are the suppling situation and the lower end of the tibia; besides which state of parts, the same malleolus is subjected to the action of the external lateral ligaments, which, spending with great force, in consequence of those ligaments being torn, nearly at a right angle with the lower end of the tibia, while this process itself is in contact with the astragalus, which is projected from within outwards by the tibia. The latter bone, being thicker and stronger than the shaft, generally remains; and if the malleolus internus sometimes happens to break, it is secondarily, as an effect of the displacement of the foot outwards.

In the other example, where the foot is twisted outwards, the centre of gravity of the body, instead of following its usual course, obliquely crosses the lower end of the tibia, the astragalus, and the malleolus internus, and falls on the ground at a greater or less distance from the inner edge of the foot.—On the one side, the internal lateral ligaments and malleolus, and on the other, the lower end of the tibia, are then the parts which have to bear the weight of the whole body and the force of the tension; and they are also the parts which are torn and fractured. First, the internal lateral ligaments, or the malleolus; and, secondly, the lower portion of the tibia.—(Anatomy of the Human Body, 1818, p. 65, 67.) Some of the symptoms of a fracture of the tibia, from an indirect cause, depend upon the fracture of that bone, and others upon the dislocation of the foot. They are divided by Dupuytren into two kinds: viz. *presumptive* and *characteristic*. The first are, the way in which the patient received his hurt; a noise or sort of crack heard by him at the instant of the injury; a fixed pain at the lower part of the tibia; a difficulty or inability of walking; some or less swelling round the ankle, especially about the malleolus externus and lower portion of the tibia. The characteristic symptoms are, an irregularity and unusual morbidness of some point of the lower end of the tibia; a swelling, which can be more or less distinctly felt by pressing upon and moving the part; mobility of the whole foot transversely or horizontally; a facility of bending the lower end of the tibia towards the tibia by pressure; a change in the point of incidence of the axis of the limb upon the foot; distortion of the foot outwards, and sometimes backwards; relaxation of the lower part upon the axis from within outwards; an angular depression, more or less manifest, at the outer and lower part of the leg; projection of the internal malleolus; disappearance of almost all these symptoms, as soon as reduction is effected by a force applied to the foot; and their immediate recurrence when such force is discontinued, particularly if the limb be in the extended posture.—(Vol. vii. p. 65.)

In considering the varieties of simple fracture of the tibia, the first to which Dupuytren adverts is that in which the bone is broken more than three inches above the articulation of the malleolus externus; a case neither complicated nor followed by any displacement of the foot, and almost always prepared by the direct application of violence to the broken part of the bone.

A second variety of simple fracture of the tibia is when the bone has been broken, either by direct or indirect force, within three inches from the end of the malleolus externus, and when the foot is not displaced, though much displacement is possible, and, indeed, often arises from the slightest effort to retract the part by the patient. The most frequent point of injury is about two inches and a half above the extremity of the lower malleolus. This is generally the place of a fracture caused by a blow of the foot outwards; but the accident may happen lower down, as is commonly

seen, when the fracture is occasioned by a blow of the foot inwards.

These fractures of the tibia, abstractedly viewed, are not of much importance in themselves; but with reference to the manner in which they facilitate the dislocation of the foot, they are very serious.

Among the most frequent complications of fractures of the tibia, are the rupture of the internal lateral ligaments, the detachment of the point of the lower malleolus, and fracture of the lower part of the tibia. When these lesions originate from a violent blow of the foot outwards, they precede the fracture of the tibia; but when they are caused by a blow inwards, they follow the breaking of that bone.—(Dupuytren, *op. cit.* p. 66.)

Besides distortion of the foot outwards or inwards, an attending certain dislocation of the tibia, another complication may be dislocation of the two tarsals, produced by the action of the muscles of the foot and not by the same causes which broke the bone. However, whenever the malleolus internus has not given way, the dislocation is incomplete, and the foot is displaced outwards as well as backwards. In the complete dislocation, as Dupuytren remarks, the foot presents a fixed invariably anteroposterior, though in a state that it will not always answer in maintaining the reduction.

TREATMENT OF FRACTURES OF THE TIBIA.

As in most of fractured thighs, the position may almost either a bent or a straight position of the limb. In this country, surgeons mostly follow Mr. Pott's advice, and select the first one, of which name I shall treat. That the best position is, generally speaking, the most advantageous for a broken leg, I am well convinced. The strong muscles of the calf of the leg are the powers which tend to displace the ends of the tibia, and their relaxation is a thing of the first consequence. It is quite different in the thigh, where the muscles are so numerous, that the strength tends, by any position of the limb, almost to have the point of displacing the fragments, would be in vain. I am ready to acknowledge, however, that in the best position the apparatus is delicate, and much to a limb and keep the knee-joint loose, but in a certain case, such motion has not so serious an effect upon fractures of the leg as it has upon those of the thigh. When the case is complicated with a wound, which cannot be dressed in the best position of the limb, without great disturbance of the patient, the straight position might happen to be preferred. With respect to one of Mr. Pott's objections to the position, viz. that it makes the knee stiff for a long while afterwards, I suspect that we should not lay too much stress upon the circumstance; because, as I have already observed, it is always the joint nearest below the fracture that is thus affected.

In the fracture of the tibia only (says Pott) the position is not of much consequence; because, as the tibia remains entire, the fibres of the leg are preserved, and continue quite uncontracted; but still, even here, the laying the leg on its side instead of on the end, is attended with one very good consequence, viz. that the confinement of the knee, in a moderately bent position, does not render it so irremediably flexed and stiff as when the straight or extended position of it does; and consequently, that the patient will be much sooner able to walk whose leg has been kept in the latter position, than he whose leg has been confined to the latter.

In the fracture of both tibia and fibula, the knee should be moderately bent, the thigh, both, and leg lying in the same position as in the former thigh. If extension appears to be used, one should be placed underneath the leg, extending from above the knee to below the ankle, the foot being properly supported by pillows, bolsters, &c., and another spinal of the same length should be placed on the upper side, compressing both joints in the same manner; which disposition of supports might always to be observed, so as that length, if the leg be laid extended in the common way, only changing the central position of them, as the pressure of the leg is changed, and calling what is inferior in one case exterior in the other; and what is superior in one, in the other inferior.

If Mr. Risbrough's splines be made use of, there is nothing of them a provision for the same easy support of the knee and ankle, by an apparatus in, and a principle

tain of the lower or tibial splint, for the purpose of keeping the foot steady."—(Pott.)

The strong muscles of the leg being relaxed by placing the limb in the best position, as advised by Pott, the surgeon is to make such extension as seems necessary for bringing the ends of the fracture into even apposition. Then he is carefully to raise the leg a little way from the surface of the bed, by taking freely hold of the limb above and below the fracture, and elevating the broken bones together in such a way as shall keep both the upper and lower portions as nearly as possible on the same level. As this cannot all be sustained should put exactly beneath the leg the under splint, which has been previously made ready by covering it with a soft pad, and laying over this an eagle-tailed bandage. The limb is now to be gently depressed till it rests on the apparatus. The surgeon, before proceeding further, must once more observe that the ends of the bones are evenly in contact. Being assured of this important point, he is to apply a piece of strip-plaster, and lay down the tube of the bandage. Another soft pad well filled with tow, is next to be put over the upper surface of the leg, and over that the other splint, when the straps are to be tightened.

Mr. Pott's method of treating fractures of the tibia is complemented with fixation of the tibia, as described in the article *Dislocation*, and Hagerup's practice in the last edition of the *First Lines of the Practice of Surgery*.

In an oblique fracture of the head of the tibia, extending into the knee-joint, Dr. A. Cooper recommends the straight position, in which the femur has the good effect of keeping the articular surfaces of the tibia firm. A roller is to be used for pressing one fragment towards the other; a plasterboard splint is also to be applied with the same view, and early passive motion of the joint is to be practiced in order to prevent ankylosis.

When the fracture is oblique, but does not reach into the joint, the same advice applies, placing the limb on the antero-internal plane.—(*Surgical Essays*, part 1, p. 302; and see *Dislocations*, &c. p. 225.)

FRACTURES OF THE SCAPULA.

As Boyer correctly observes, fractures of the scapula are not very common; a circumstance explicable by the deep and covered position of the greater part of this bone, and its great mobility. Nor are these accidents attended with considerably direct violence. However, there are some parts of the scapula, which, being more superficial, and of a form more likely to be acted upon by external bodies, are more frequently fractured: such are the acromion and anterior angle of the bone. Fractures of the coracoid process, and even of the neck of the scapula, are also mentioned; but the occurrence of such accidents are not common; and though these parts of the bone may appear at the shoulder, they do not often break, their deep situation in the bony subject generally saves them. Indeed, as Boyer says, they generally require great violence to break them, and then the cohesion of the soft parts is a worse injury than the fracture itself; thus, one author has seen the coracoid process broken by the blow of the point of a cleaver, and the patient lose his life from the violence at the same time inflicted upon all the soft parts about the shoulder.—(*Nouveaux Méthodes*, t. 2, p. 44.)

When the acromion is broken, the weight of the arm, and the contraction of the deltoid muscle, draw it downwards, while the trapezius and levator scapulae draw the rest of the bone upwards and backwards. The position of the injured shoulder is lost, and part of the attachment of the deltoid being broken off, the head of the os humeri tends towards the axilla, as far as the capsular ligament will permit. On tracing the movement from the apex of the scapula to the clavicle, the surgeon will find a depression just at their junction. The distance from the sternal end of the clavicle to the extremity of the shoulder is lessened. The natural form of the shoulder may be restored by raising the arm by the elbow; but the intensity requires immediately the arm is suffered to fall again. The axilla may be distinguished from a dislocation, if the surgeon upon the shoulder by passing the humerus upwards, when a creping will be perceptible to the surgeon's hand applied over the acromion, the arm being rotated.—(A. Cooper on *Dislocations*, &c. p. 45.)

When the lower angle is broken, the acromion major articulus draws it forwards, while the rest of the scapula remains in its natural situation; or if the angular portion be considerable, the trapezius, and some fibres of the latissimus dorsi, contribute to its displacement forwards and upwards.

When the coracoid process is fractured, the pectoralis major, coraco-brachialis, and short head of the biceps current in drawing it forwards and downwards.

When the neck of the scapula is fractured, the weight of the arm makes it drop down as considerably as to give the appearance of a dislocation; but the facility of lifting the arm fractis upwards, the creping, and the falling of the limb downwards again, immediately it is unsupported, are circumstances clearly marking that the case is not a dislocation. According to Dr. Hunter Cooper, the creping is best perceived through the medium of the external process. The degree in which the glenoid cavity and the head of the humerus descend, as observed, depends very much upon whether the ligament between the upper part of the spine of the scapula and the glenoid cavity is lacerated or not.—(See *Dislocations*, &c. p. 459.)

Sometimes great pain and a creping are experienced on moving the shoulder-joint after an accident; and yet the spine, the neck of the scapula, and all the above parts, are not broken. In this circumstance, it is to be suspected either that a small portion of the head of the os humeri, or a little piece of the glenoid cavity of the scapula, is broken off; which latter occurrence, I think, is not very uncommon.

When the inferior angle is broken the post-segment is extended, while the rest of the scapula is moved; and it is so arranged, that no mistake can be made.—(Boyer.)

Fractures of the spine and body of the bone are all attended with a creping; but in the first cases, an irregularity of the osseous part may possibly be felt.

The prognosis of fractures of the scapula varies according to the situation of the injury, and the attendant circumstances. Fractures of the body of the bone, whatever may be their direction, are generally very simple and readily cured. Those of the acromion and lower angle are more troublesome to keep right; but the most serious cases are fractures of the coracoid process and neck of the bone, which cannot be kept tight without great difficulty, and are said to be frequently followed by a considerable stiffness of the arm, tending to render it, in any way, and even paralysis. In other respects, the danger of fractures of the scapula depends less upon the situation of continuity at the bone, than the extension of the soft parts or injury of the thoracic viscera. However, when the fracture is comminuted and the splinters are forced into the subscapularis muscle, abscesses may form under the bone, and, according to Boyer, require a perforation to be made in it (*Med. Chir. t. 2, p. 365*), a proceeding which I cannot bring myself to think would ever be judicious, as making a penetrating opening in the soft parts must be the least possible. In military surgery the scapula is often injured by sabre-cut; but as Dr. Hunter remarks, this bone, when preserved from infection, is found in some cases to unite with great rapidity and without future inconvenience.—(*Principles of Military Surgery*, t. 2, vol. 2.)

According to Boyer, when the scapula is fractured longitudinally or transversely, it is merely necessary to fix the arm to the side by means of a bandage which includes the arm and trunk from the shoulder to the elbow. Thus the movement of the shoulder, which are only inconsistent with those of the arm, are prevented.

When the inferior angle is broken and drawn downwards and forwards by the acromion major articulus, the scapula must be pushed towards the humerus by inclining the arm itself upwards, downwards, and forwards, while it is to be kept with a roller. The humerus is also to be kept backwards as much as possible with compresses and a roller, and the arm is to be supported in a sling.

The fractured acromion requires the arm to be sustained that the head of the os humeri will push up the acromion, while an assistant pushes the scapula forwards and downwards in a contrary direction to that of the arm. To maintain this position, a circular bandage is to be applied round the arm and body.

Drawn tend to apply over a small pillow under the axilla before putting on the bandage, in order to make

the head of the os brachii project more upwards on bringing the arm out the side, but the Author Cooper thinks that a pillow on placed deep burns by throwing the head of the os brachii upwards, and widely separating the scapula from the spine of the scapula. He opposes the raising the elbow and keeping the arm fixed. He now retains the distal fracture by means of a medium put between the elbow and the side, the elbow keeping a little forwards; the limb is not to be brought to the chest in this position with a roller. The sides may have place by hand, but owing to the difficulty of maintaining the position, the writer recommends a permanent apparatus. — (A. Cooper on Bone Fractures, p. 455.)

When the external process is fractured, the bone is attached to it as to be relaxed by bringing the arm forwards towards the breast and keeping it there as a sling, while the shoulder is kept downwards and backwards, and a compress is placed just under the broken part with a roller.

The treatment of a fracture of the neck of the scapula consists in keeping the head of the os brachii upwards by means of a thick cushion in the axilla; in keeping the elbow bent and arm raised with a sling; and in preserving all motion of the arm by sliding it to the trunk with a roller. In case of these cases the apparatus proposed by Mr. Earle might be very useful. — (Pract. Med. in Surg. 1822.)

FRACTURES OF THE CLAVICLE.

This bone, being strong and slender, is supported at its ends, and protected externally only by the integument, is very often broken. In striving to keep the scapula at a proper distance from the scapula, and as a point of support for the os brachii, every degree of which recovery makes the fracture still more complete.

It may be broken at any part; but its middle, where the curvature is greatest, is most frequently the situation of the injury. It is not very often fractured at its extremity extremely. However, a direct force falling on the shoulder may break any part of the clavicle on which it immediately acts. The soft parts in this kind of case are also not so much injured.

A compressed fracture may be thus examined, and if the symptoms be very great, the subclavian vessels and nerves may be torn. The fall of a heavy body on the shoulder often gives rise to a paralysis of the arm.

When the fracture first is applied to the side of the bone, so as to fall on the point of the shoulder or on the humerus under the arm are extended, the clavicle may be very much bent, and fractured so obliquely, that the broken portions protrude through the skin.

Fractures of this bone are usually attended with displacement, except when the injury takes place at the scapular extremity and within the ligament, tying the clavicle and coracoid process together.

The external portion of the clavicle is always that which is displaced. The internal part cannot be moved out of its natural situation by reason of the costoclavicular ligament, and of its being drawn in opposite directions by the sternal-cleido-mastoid and posterior axillary muscles. The external portion, drawn down both by the weight of the arm and the action of the axillary muscles, and forwards and towards the pectoralis major, is carried under the external portion, which projects over it. The broken clavicle no longer keeping the shoulder at a due distance from the sternum, the arm falls forwards towards the breast. The position thus it is impossible to put the hand to the forehead because the arm is not so much in a horizontal position as the humerus necessary, which cannot be done while the arm has an arm power of support. The shoulder and upper extremity may be observed to be nearer the breast than that of the opposite side. The motion at the joints of bones on one another may be lost, as well as the projection of the end of the internal portion. When the shoulder is raised a crepitus may also be perceived; but this is productive of great pain, and the diagnosis is so obvious that it is quite unnecessary.

The ancient, and many modern, have supposed, that, in order to set a fracture of the clavicle, the shoulder must be drawn back, and fixed in that position. The patient was placed on a large stool, so that an assistant might put his knee between the shoulders, which he drew back at the same time with both hands, while the surgeon applied the bandage which was to keep the

parts in this position. But when the shoulders are thus drawn towards one another, the clavicle is necessarily pushed towards the sternum, and with it the external portion of the clavicle, which passes under the internal fragment.

The figure of a bandage has commonly been used for maintaining the parts in this position. While the shoulder keeps back the shoulder, as above described, the surgeon is to apply one end of a roller to the front of the side of the neck, and then apply a cross bandage to the opposite shoulder, round which it is to pass, and from that to the other shoulder, about which it is to be applied in the same manner, and afterwards repeatedly crossed before and behind. The tightness with which it is necessary to apply this bandage produces a great deal of excoriation about the axilla, and the effect is to make the ends of the fracture every inch nearer, the very thing which it is wished to avoid. Hence we think, that the true cross proposed by Hunter, as correctly described by Brander in the *Plan de l'Art de l'Art de l'Art*, and the roller strap recommended by Dupuytren, are very modifications of the figure of a bandage, and are not at all better.

Desault advised, however, to be made by means of the limb, which is applied with the modified bandage. This is done by converting the bandage into a loop, by carrying its lower end forwards, towards, and upwards, passing the shoulder back with a spiral and upwards, and putting a station to the upper end as a fulcrum.

Desault used to put in the axilla a bar of buckram, five or six inches long, and three inches and a quarter thick at its base. Two straps are stretched to the ends of the bar, which is placed upwards. They cross the back and breast, and are tied to the middle of the other arm. The cushion being thus placed in the axilla, and the bar in the hand, Desault used to take hold of the patient's elbow, and carry it forwards by means, and towards, pressing it slowly round the breast. By this motion, the fractured clavicle is drawn towards the sternum, the ends of the bones become situated opposite each other, and all difficulty is removed.

An assistant is to support the arm in this position, while the surgeon, taking a single-headed roller or one yard long, is to place one end of it in the axilla at the opposite side, and then apply the bandage with the upper part of the arm, and across the back to the same situation. The arm and trunk are to be carried with such circles of the roller, as far down as the elbow, drawing the bandage more tightly the lower it descends.

Compresses, dipped in camphorated spirit, are used to be placed along the fractured bone. Desault took a second roller, of the same length as the first, and put one end of it under the opposite axilla, where it was carried across the breast over the compress and fracture, then down behind the shoulder and arm, and after having passed under the elbow, directed to the breast. Desault next brought it across to the second shoulder, under and round which he laid it, for the purpose of fixing the first turn. He then crossed the roller across the back, brought it over the compresses, carried it down in front of the shoulder and arm, under the elbow, and obliquely behind the back to the axilla, where the application began. The same plan was repeated, until all the roller was spent. The apparatus was secured by pins, whenever they presented to be useful, and the patient's hand was kept in a sling.

Keyer has invented an apparatus for fractured clavicles, which is more simple than that proposed by Desault.

The cushion is to be applied under the arm. The apparatus consists of a grille of iron cloth, with passes round the trunk on a level with the elbow. It is fixed on by means of three straps and is many inches as an equal distance from the scapulae, the plates extending to each side two inches, two below and two behind the arm. The lower part of the arm is supported by a piece of quilted cloth, five or six inches broad. Four straps are attached to it, which are passed to the back of the outside of the grille, and serve both to keep the arm close to the trunk, and from turning the back towards or forwards.

Certainly, the methods proposed by Desault and Keyer are very judicious and scientific. They are, however, much adopted in this country, perhaps more

importance of the general exercises among English surgeons in every apparatus which is not especially contrived. It is to be feared, at the same time, that in the treatment of fractured clavicles, they will always attend to the particular which Desault and Boyer have mentioned. If they understood why the position of the arm should be such as those frequent fractures point out, they will have no difficulty in doing what is proper, and with a cushion, sling, and a couple of rollers, they will supply means to the proper position. A simple and appropriate apparatus for fractures of the clavicle, and those of the neck of the scapula, has been recently proposed by Mr. Davis. (See the *Practical Observations on Surgery*, p. 187, &c.) It is also calculated for cases of dislocated clavicle, and other injuries of the shoulder.

I cannot quit the subject without expressing my great regret to find the error of supposing the movement of a broken clavicle to be the end which is required. This is the one which is truly an *in situ* treatment, and which has often been made, by anxious persons, to promote through the misapprehension, never in instances of which have failed under my own observation.

Until within a few years, fractured clavicle was almost universally treated in this country by Desault's bandage. The objection to it has been apparent for some time. Nevertheless, when applied, it is adequate to fulfil all the indications necessary in this kind of injury, yet its complexity, its liability to be changed, and the pressure it makes upon the axilla in many patients, rendered a substitute highly necessary every desirable. Dr. Joseph H. Coak, of Baltimore, constructed an apparatus, in 1835, for this purpose, which in his hands was entirely successful in his cases of oblique fracture of the clavicle, and was highly recommended by Drs. Foster, Dozette, and Gibson, of the University of Maryland. It was made of leather straps and buttons, performing the triple purpose for which Desault's bandage was adapted, and its simplicity as well as its portability, together with its superiority to former patients, has brought it into general favour in the south. Dr. Northing, of New-York, has introduced to the profession an improvement or modification of Desault's bandage, which is now in general use in many parts of the United States. It consists of a white flannel roller, seven yards long, and three and a half inches wide, the circumference of which end so perfectly simple, that a description of the method will be superfluous to enable any practitioner to apply it with readiness and facility.

A full description of this apparatus may be found in the 4th vol. of the *Am. Med. Recorder*. And as it fulfils every necessary indication, without being liable to the objections which are known to exist against that of Desault, it is well worthy of the confidence of surgeons generally; and, indeed, it possesses in this country altogether to supersede it.—*Edin.*

FRACTURE OF THE CLAVICLE IN INFANTS.

The bone may be fractured in any point of its length; across the middle, either at the extremities, or above the insertion of the posterior muscle, between the scapula and the sternum. The last case is termed fracture of the neck of the humerus; but that denomination has the merit of being strictly anatomical. It is possible, however, the bone may be strictly called the neck of the humerus, may be fractured perfectly by a gun-shot wound. In such of the humerus, we understand that circular sawing which separates the tuberosity from the head.

The fracture of this bone may be transverse or oblique, simple or compound. Transverse fractures, in the middle part, below the insertion of the deltoid muscle, are attended with but little displacement, for the deltoid muscle and the biceps, being attached posteriorly and anteriorly to both fragments, contract one another, and allow only a slight angular displacement. When the fracture takes place above the insertion of the deltoid muscle, the inferior portion is first drawn outwards and then upwards on the external side of the superior. Fractures of the humerus, near its lower end, such particularly as are oblique, are not subject to much displacement; a transverse one is attributed to the breadth of the deltoid muscle; in their being covered posteriorly by the triceps muscle, and anteriorly by the brachialis muscle, which allows only a slight angular displacement, by the inferior portion being drawn a little forwards.

Oblique fractures are always attended with displacement, whatever be the part of the bone broken. The superior portion being drawn upwards by the action of the deltoid muscle, comes out to the side, and the inferior portion of the humerus, which rests on the superior, and passes above or lower externally. Finally, fractures of the neck of the humerus are always attended with displacement, produced by the action of the posterior muscle, between the scapula and the sternum, which, being attached in the lower portion near its insertion, draws it first upwards and then forwards, in which last direction it is powerfully urged by the biceps, coracobrachialis, and long portion of the triceps. In this case, the superior portion itself is directed a little upwards by the action of the infra-scapular, supraspinatus and other muscles, which raise the head of the humerus from a rotatory position in the glenoid cavity.

The succeeding swelling in the direction of the limb, the swelling, which may be very distinctly perceived by passing the broken pieces in opposite directions, the pain, and impossibility of moving the arm, &c., joined to the history of the case, render the diagnosis sufficiently plain.

Fractures of the neck of the humerus, however, are not so easily ascertained, and, though want of attention, have been frequently misdiagnosed with lesions of the bone. Yet the diagnostic symptoms of these two affections are very different.

When the neck of the humerus is fractured, a depression is observed at the upper part and external side of the arm, very different from what accompanies the fracture of the bone downwards and upwards. In the latter case, a deep depression is found, just below the insertion of the acromion, in the natural situation of the head of the humerus; whereas, in fracture of the neck of that bone, the shoulder remains in its natural position, the acromion does not project, and the depression is found below the point of the shoulder. Besides, on raising the arm, instead of finding there a rotatory motion, played by the head of the humerus, the fractured end, though sufficiently of that bone will be easily distinguished. The motion of the broken portion, and the crepitation thus produced, serve still further to establish the diagnosis.—*Edin.*

In a simple fracture of the body of the humerus, the prognosis is generally favourable; but fractures near the elbow are liable to be followed by some loss of stiffness of the joint, often very difficult to correct.

In ordinary fractures of the os humeri, it is usual to apply two pieces of soap-plaster, which together surround the limb, at the situation where the accident has happened. Extension, if necessary, being now made by an assistant, who at once draws the lower portion of the bone downwards and bends the elbow, the extension is to apply a roller round the limb. The external object is to extend from the insertion to the outer condyle, and being fixed with a soft pad, the wool cannot hurt the limb by pressure. The internal object is to reach from the margin of the axilla to a little below the outer condyle, and as is to be well guarded with a pad, filled with wool, or any other soft material.

Some surgeons are content with the application of two splints; but though the two above described are those which we are to place the greatest reliance, yet as the cylindrical form of the arm so conveniently allows us completely to surround this part of the limb in splints, I consider the employment of four better: one on the outside, one on the inside, one on the front, and another on the back of the arm. These are to be carefully fixed in their respective situations by means of tape.

Throughout the treatment, the elbow and wrist of the forearm are to be quietly and effectually supported in a sling.

FRACTURE OF THE SHAFT OF THE OS HUMERI.

Oblique fractures here differs from that adopted by Desault, and, under the name of fracture of the neck of the humerus, is not meant that of the casting, nearly perpendicular depression, which separates the head from the tuberosity of the bone. In this expression, surgeons imply the fracture of that contracted part of the humerus, which is located above by three oblique lines; which below is continuous with the body of the bone, which has the tendons of the posterior triceps, brachialis, and coracobrachialis inserted below it; and

which entry practitioners would attribute to the situation of the external angle.

Informative facts, however, prove the possibility of the anatomical neck of the bone being fractured, and it is well known that the humerus of a young man, aged 17, the head of which bone was severely crushed from its body, by a fracture which had passed obliquely through the upper part of the tuberosity. Another example, proved by dissection, has been very lately recorded by Hilcock. (Chirurgie Clinique.) An instance of this kind, I think, was pointed out to me in the spring of 1831, in St. Bartholomew's Hospital. The patient was a boy, whose elbow had been strongly kept up, on the supposition that the case was a fracture of the neck of the humerus, and, consequently, the irregular end of the humerus formed a considerable projection in front of the scapula, yet capable of being pushed back, where, however, it would not remain. When the accident is produced by a direct blow or fall on the fleshy part of the shoulder, the dislocation is sometimes contained and affected with erysipelas. Even blood may be effused from some of the ruptured arterial vessels of the artery, and form a collection which demands recumbency to be speedily opened, though the reason of such practice, as a general thing, must be questionable, because large extravasations of blood about the shoulder are usually very soon absorbed.

Mr. Astley Cooper has mentioned several both in old and in young persons; but according to his observation, it rarely occurs in middle age. In the young, he says, it happens at the junction of the epiphysis where the cartilage is situated; and in the old it arises from the greater softness of this part of the bone. (On Dislocations, &c. p. 450.)

An simple joint is experienced at the moment of the fall; sometimes the issue of something breaking is heard. There is always a sudden inability to move the limb, which, left to itself, remains motionless. But, on external force being applied, it readily yields, and admits of being moved with the greatest ease in every direction. Much tension is attended with severe pain, and, if carried too far, may cause its relaxation; as has been observed in palsy in which the fracture has been mistaken for dislocation.

Below the scapula a depression is remarkable, always situated lower down than that which attends a dislocation. If we place our hand on the head, while the lower part of the bone is moved in various directions with the other hand; or if, while extension is made, an assistant commences to move the lower a rotatory motion, the following circumstances are perceived. 1. The head of the humerus remains motionless. 2. A more or less distinct crepitus is felt, arising from the two ends of the fracture rubbing against each other. These two symptoms are characteristic of the accident; but the swelling of the joint may prevent us from detecting them.

Sometimes there is no displacement of the ends of the fracture, and then, as most of the symptoms are absent, the diagnosis is still more difficult. In general, however, the ends of the fracture are displaced, and in this circumstance it is the lower one which is out of its proper position, and not the upper one, which is held up, as is the case upon many accidents.

The displacement is generally not very perceptible in regard to length, unless the fracture be very oblique, and the pointed epiphysis retains the position, and make them contract with increased power; or when the blow, which was very violent, continued to operate after the bone had been broken, and forced the ends of the fracture from their state of apposition. In this way the body of the humerus has been driven or driven downwards, so as to protrude through the deltoid muscle and pinnascent for above the height of the head of the bone.

But commonly, as Pott observes, the weight of the two powerfully tends the union of the scapula, and the displacement of the fracture is more likely to be transverse. In that circumstance the lower end of the fracture is displaced upwards or forwards, and rarely in any other direction. In the most frequent case, the elbow is separated from the trunk, and cannot be brought near it without pain; and in the extreme of the bone being displaced upwards the limb has a tendency to the opposite direction. According to Mr. Astley Cooper, the upper end of the main portion of the humerus sticks into the scapula, where it can be felt, and the

distal is drawn down by it, so that the two ends of the shoulder is diminished. (On Dislocations, &c. p. 451.)

The reduction takes place of itself on employing a very little force methodically directed, according to the fracture is displaced upwards or forwards. If the surgeon put his hands on the situation of the fracture, it is easier to estimate the state of the ends of the bone, than it is to accomplish a thing without touch, namely, what is inspired by the bone contacted.

Every apparatus for the cure of fractures being only recommended by art in the patients causing the displacement of the broken part, it follows that the whole should not be in an inverse ratio to each power. These cannot, 1. Of the action of external bodies, formed by the extreme mobility of the arm and shoulder; 2. Of the action of the latissimus dorsi, pectoralis major, and other muscles, which draw towards the lower end of the humerus, or of the deltoid, which pulls upwards; 3. Of the continuities of the reaction of the arm, which tend to contract the end of the fracture in a little space.

Before, in the treatment, the three indications are, 1. To render the arm and shoulder immovable. 2. To bring either upwards or upwards the lower end of the fracture. 3. To draw downwards the same. The last object requires less attention than the two others, because the weight of the arm is alone almost sufficient for the purpose. Determined to employ the following apparatus.

1. Two long rollers. 2. Three strong splints of different lengths, and between two and three inches wide. 3. A cushion or pillow, three or four inches thick, as one of its ends, terminating at the other a corner point, and long enough to reach from the axilla to the elbow. 4. A sling to support the forearm. 5. A band to cover the whole of the apparatus.

The patient having been elevated, the apparatus are to be confined the extremities. Then the splints are to take the first roller, which is to be put over the epiphysis, wrist, and elbow, and be so to the one of its limbs or applying two splints, three in the upper part of the forearm. The shoulder is next to be held immovable, tight round the arm upwards, making such an oval as will enclose the arm which is immovable below it. When the roller has reached the upper part of the arm, it must be doubled back a few times to prevent the folds which the irregularity of the part would cause. The bandage is afterwards to be passed first under the opposite axilla, and the rest of it, rolled up, is to be brought up to the top of the shoulder, and continued to the arm of an assistant.

The first splint is to be placed in front, reaching from the bend of the arm as high as the scapula. The second, as the outside, from the axillary angle to the same height. The third, behind, from the extremity to the middle of the scapula. The pillow, inserted between the arm and thorax, serves as a firm point, which becomes motionless. An assistant upon these parts of the apparatus, and holds them in by applying his hands under the bend of the arm, in which is constructed the application of the remainder of the bandage.

The surgeon takes hold of the bandage again, and applies it over the splints with moderate tension, and the bandage ends at the upper part of the arm where it began.

While the assistants still keep up the extension, the surgeon is to place the pillow between the arm and thorax making care to put the thick end upwards, if the fracture be displaced upwards, and downwards if it should be displaced downwards, which I should most earnestly. Then the pillow is to be fastened with two pins to the upper part of the roller.

The arm is to be brought near the trunk, and held upon the pillow by means of the second roller applied round the arm and thorax. The turn of this bandage should be pulled tight below and above, when, if the fracture be displaced upwards; but if upwards, it should be drawn below and tight above.

The forearm is to be supported in a sling, and the whole of the apparatus is to be covered in a cloth, which will prevent the bandages from being pulled out of their places.

If the effect of the above apparatus is following the indications above specified is considered, we shall find that they are very well accomplished. The two splints fixed against the trunk, can only move upwards, and then nothing displaces the lower end of the fracture, which is equally motionless. The shoulder can

not contraindicated any motion to the upper end of the fracture. The pillow, differently disposed, however, in the direction in which the lower extremity of the fracture is displaced, serves to keep this part in the opposite position.

Should this part of the bone grow upwards, the thick end of the pillow will remove it farther from the chest. The bone will be kept in this direction from the side by the action of the humerus, which, being very tight downwards, will act upon the trunk as a lever, the fulcrum for which will be the pillow, and the resistance the action of the pectoralis major, latissimus dorsi, and triceps major. Thus the humerus will have the effect of bringing the elbow nearer the trunk, and move the lower end of the fracture in the opposite direction, so that it may here be considered as an artificial muscle directly opposing the natural ones.

When the lower end of the fracture is drawn downwards, the contrary effect will be produced, both from the pressure exercised by the humerus on the upper end of the displaced portion of the bone, and from the situation of the elbow; which is kept up by the thick part of the pillow. The outer angle will also prevent the lower end of the fracture from being displaced outwards, both by its mechanical resistance to the lever, and by compressing the internal muscles, which is the chief cause of such displacement. All displacement of the lower end of the fracture forwards or backwards is prevented by the thick pillow; and as for the longitudinal displacement, which is already prevented by the weight of the arm, it is still more effectually hindered by the compression of the muscles of the arm both by the upper and outer angles—see *Illustrations*, &c. p. 303, fig. 13.

Dr. Aitken, Cooper recommends a roller to be applied from the elbow to the shoulder, and, two splints to be bound on the inner and outer sides of the arm with a roller; a cushion is placed in the axilla in order to throw out the head of the bone; and gentle supporting the arm in a sling. Should the elbow be much raised, he says, the bones will overlap, and the splint be attached with difficulty.—(*On Dislocations*, &c. p. 303.)

FRACTURE OF THE LOWER END OF THE CLAVICLE, WITH SEPARATION OF THE COSSIDES.

Fractures of the os humeri, with detachment of its condyles, seem to have engaged the notice of most authors who have written on the diseases of the bones. The ancient, however, in this circumstance, and Denham in particular has frequent occasion to meet with it.

Whatever its causes may be, the two condyles are usually separated from each other by a longitudinal division, which extending more or less upwards, is bounded by another transverse or oblique division, which occupies the whole thickness of the bone. Hence, there are three different pieces of bone and two fractures.

Sometimes, the division is more simple; as when, taking a direction upwards or forwards, it crosses obliquely down the lower end of the os brachii, separates in the joint, and only fractures one of the condyles from the body of the bone.

In the first case the recovery is sooner, and the fractured part is more movable. When pressure is made either before or behind, on the thick of the longitudinal fracture, the two condyles, becoming farther separated from each other, leave a space between them, and the fractured part is relaxed. The humerus is almost always in a state of ossification. On taking hold of the condyles and moving them in different directions, a distinct crepitation is perceived.

In the second case, the separation of the condyles from each other is not so easy; but a crepitation can always be distinguished on moving the detached condyles. As, however, in which only the external condyle was broken, Denham found the arm always rigid; a point on which the exercise consisted in that part were, doubtless, concerned in producing.

In both cases, as we have seen, the almost inevitable effect of bending or extending the humerus; an habitual habit most state of this part of the limb, and sometimes a subsequent swelling of it, together with more or less inflammation round the joint, are observable. When the elbow has been very violent, or a pointed piece of the bone protrudes through the skin, the accident may be complicated with a wound, or even of bone, &c.

When the condyles of the humerus are obliquely

broken off just above the joint, the appearance, as described by Sir Astley Cooper, are those of a dislocation of the humerus and ulna backwards; but the nature of the case is evinced by the immobility of the distal-terminus rotating as soon as the extremity is moved, and also by the crepitation, generally perceived when the humerus is relaxed upon the thorax.—(*On Dislocations*, &c. p. 421.)

The old writers consider the communication of a fracture with a joint a fatal kind of complication. Swelling and inflammation of the adjacent parts; ossification of joint after the reduction; large abscesses, even mortification of the soft parts, and various of the bones, are, according to such authors, the almost inevitable consequences of these fractures, and undoubtedly the most formidable termination. Paré, Feut, Heister, Diemerbroeck, all give this exaggerated opinion. However, analogous illustrations of the contrary and positive prove that this representation is misplaced beyond truth. Modern observation has depicted the various degrees of the extension of effusion into the joint, and with a view of the principal causes assigned by authors for the symptoms so much dreaded.

The detached condyles being drawn in opposite directions by the muscles of the arm and thorax, necessarily again removed between their two points, and are but little displaced. Natural force may, however, put them out of their proper situation, and they may then be displaced forwards or backwards, or they may separate from each other entirely, leaving an interspace between them. Hence, the separation should occur there in these four directions, and this object is easily accomplished by means of four splints kept on with a roller. The two lateral splints are particularly necessary when the condyles are separated from the body of the bone with an interspace between them. If one of them be still continued both the humerus, as well as this side will be positive.

The apparatus used, and extend as high as when the arm is fractured higher up; but the roller should be continued over the thorax, in order that the joint may correspond to the middle of the humerus, which should here be firmer than any where else. This method is also of use in producing a gentle compression of the muscles applied into the condyles. Denham recommends the front and back splints to be flexible at their middle part, which should be applied to the head of the arm and elbow.—(*Illustrations*, &c. p. 303, fig. 13.)

The treatment advised by Sir Astley Cooper consists in bending the arm, drawing it forwards as far as to reduce the parts, and then applying a roller. The two splints for this case, he says, is one, bound at right angles, the upper portion of it being placed behind the upper arm, and the lower under the forearm. He also directs the application of a splint to the fore part of the upper arm. The splints are to be fixed with waxes; evaporating lotions used; and the arm kept in a bent position in a sling. In a fortnight, if the patient be young, and in three weeks if he be an adult, passive motion may be gently employed for the purpose of hindering an anchylosis.—(*On Dislocations*, &c. p. 422.) According to the same author, when the internal condyle is broken off obliquely, the arm bears its natural support and projects backwards.

FRACTURE OF THE FOREARM.

The forearm is more frequently broken than the arm, because external force operates more directly upon it than the latter part, especially in falls on the hands, which are frequent accidents. Hence in the account of Denham's practice, we find that fractures of the forearm often hold the first place in the comparatively of such cases kept at the elbow-joint.

We know that the forearm is composed of two bones, the ulna and radius. The last of which more liable to fractures than the first, because it is much harder with the hand by a large surface, and all the muscles received by the latter part are concentrated to it. The situation of it also more immediately exposed to such causes as may break it. However, both the bones are frequently broken together.

FRACTURES OF BOTH BONES.

May occur in the extremities or middle of the fore arm. They are frequent at the middle, very common below, but seldom happens at the upper part of the

firmness, where the laminae meet, and the considerable thickness of the alvea, must causes which would either give rise to the accident. The bones are usually broken in the same line, but sometimes in two distinct directions. The fracture is almost always single, but in a few instances it is double; and the wrist, or generally, was one day visited by a patient, that while through the whole of a cart had passed, so as to break fractures at their middle and lower part, into six distinct portions. The middle one, notwithstanding they were quite detached, united very well with hardly any difficulty.

These accidents are most commonly occasioned by direct external violence; but sometimes they are produced by a contusion, which is generally the case when the patient falls on his head. But in this instance, as the hand is principally concerned with the lower bone anterior surface of the radius, this bone seems less to sustain almost the whole shock of the blow, and hence is usually the only one broken.

The symptoms indicating fractures of the forearm are not likely to lead the surgeon into any mistake; motion at a part of the limb where it was previously inflexible; a crepitus, almost always easily felt, when there is distinct depression in the situation of the fracture; occasionally a projection of the ends of the fracture beneath the skin; pain on moving the part; a small swelling attended to the patient at the moment of the accident; an inability to perform the motion of pronation and supination; and an almost constant half-bent state of the forearm.

There is one case, however, in which the fracture being very near the wrist-joint, similar appearances to those of a dislocation of this joint may arise. But attention to whether the stated symptoms are shown or below the elbow will discover whether the case be a fracture or dislocation. In a fracture, the part is more or less movable, and there is crepitus—(compare *Chr. & Deane's*, pp. 104, 113.) According to Boyer, the two cases may be distinguished by merely moving the hand; by which motion, if there be a fracture without fracture, the typical prominence of the radius and ulna will not change their situation; but if a fracture exist, they will follow the motion of the hand.

The continuity of the two bones at the forearm by the interosseous ligament, which occupies the interspace by which they are separated, and the vessels in which the vessels situated in both are inserted into them, render any displacement of the broken pieces into the Medullary direction very difficult, and in reality, such displacement is seldom observed, and never in any considerable degree. When it does take place, it is to be ascribed to the cause of the fracture, rather than to vascular contraction. The mobility, with interosseous displacement, the first piece represents the middle, and the interosseous space is dislocated or entirely obliterated near the distal end of the radius, attended with great laceration of the part. There is an angular displacement which the fragment causes always produced, either forwards or backwards, according to its direction.

Boyer gives the following account of the treatment of the fracture of both bones of the forearm.

The forearm is to be bent to a right angle with the arm, and the last is placed in a position between the pronator and supinator. The forearm and hand being thus placed, an assistant takes hold of the first finger of the patient, and extends the fractured parts, while another assistant makes counter-extension by fixing the forearm with both his hands. By these means the operator is enabled to reduce the bones to their natural situation, and so push the soft parts into the interosseous space; by a gentle and gradual pressure on the anterior and posterior sides of the arm.

The bones are kept in their place by applying first on the anterior and posterior sides of the forearm two longitudinal and graduated compresses, the ends of which is to be in contact with the skin. The depth of these compresses should be proportioned to the thickness of the arm, corresponding to the diameter of the arm diameter. By the next piece, the surgeon takes a single-headed roller, about six yards long, and makes three turns of it on the fractured part; he then descends to the hand by circles partially placed over one another, and envelopes the hand by passing the bandage between the thumb and index finger. The bandage is now carried upwards to the wrist, and then, and re-

turned wherever the frequency of the stroke may make it necessary. The compresses and bandage being thus far applied, the surgeon lays on two splints, one anteriorly, the other posteriorly, and applies the remains of the bandage over them. The compresses and remains should be in the same length as the forearm. It must be taken to employ lateral splints in this case, being what is commonly used to be reported by most books; a displacement should have taken place in that degree. Lateral splints would counteract the compression by two other splints, by lowering the transverse diameter of the arm, and with the action of the fingers, tend to push the ends of the fracture into the interosseous space. The surgeon's attention should be particularly directed to preserve the interosseous space; for, if this be obliterated, the radius cannot return to its place, nor the motion of pronation or supination is restored; and this defect may be obtained with facility by applying the compresses and splints in their position, that the fleshy parts may be drawn out and confined in the interosseous space, and by drawing the bandage every seven or eight days.

If the fracture be simple, and the exposure moderate, the patient need not be confined to bed, but may walk about with the arm in a sling.

SWELLINGS OF THE RADII

Are the most frequent of those of the radius. The radius being almost the sole support of the hand and guided to the same line with the ulna, it is more than three times more exposed to fractures than the ulna.

Fractures of the radius, whether transverse or oblique, near the middle part or extremity, may be caused by a fall or blow on the osseous, or it happens in most cases, by a fall on the point of the hand. When likely to fall we extend our arm, and in the hand, the first is the point, in which case, the radius is pressed between the hand and the ground, and the forearm, from which it receives the whole momentum of the body, is bent, and if the fall be sufficiently violent, breaks near the lower end of the middle part. When after an accident of this kind, pain and difficulty of performing the motions of pronation and supination is perceived, the probability of a fracture of the radius is very strong. The radius is fully examined by passing with the fingers along the external side of the bone. Also, in endeavouring to perform supination or pronation of the hand, a crepitus and a motion of the broken portions will be perceived. When the fracture gives place near the head of the radius, the diagnosis is more difficult, on account of the depth of soft parts over the part of the bone. In this case, the thumb is to be placed under the external condyle of the ulna, and on the superior convexity of the radius, and as the space into the hand is to be brought into the pronator and supinator positions. If in these trials, which are always painful, the head of the radius rests immovably, there can be no doubt of two bones being fractured. Here the cause of displacement was force as in fractures of the forearm; it can never take place except in the direction of the diameter of the bone, and is opposed externally by the action of the pronator supinator. The same weakness appears in fractures of the radius; and the radius is usually fractured in the middle, and is another throughout its whole length.

In general, when only the radius is fractured, the treatment is requisite. During the treatment, the hand is to be bent, and the hand put in the supinator position, and supported; that is to say, the palm of the hand is to be the patient's breast. Having reduced the ends of the fracture when they appear to be displaced, the wrap plaster is to be applied, and over this a thick roller. This bandage is, indeed, of no utility; but it makes the limb seem, in the supporting bystanders, more comfortable than if it were motionless. However, no one can doubt, that tight bandage may not very pertinaciously, by pressing the parts and often together, causing them to grow in such a way, as at all events, making the fracture case in no good way. Only two ligaments are necessary; one to be placed along the inside, the other along the outside of the forearm. Such pads must always be placed between the skin and the splints, in order to avoid the pressure of the hard materials of splints, and to prevent sores. The inner space should extend to about the last joint of the fingers, but not completely to the last

as caused by the *fungus*. We learn from Hirsch, that more than one-third of the patients on whom he had operated for supposed carcinoma of the eye were really victims of fungus. Twenty out of twenty-five cases of fungus in the cornea of the eye, with which Mr. Wainwright has been acquainted, happened to children under twenty years of age. Now, as fungus is rather a disease of aged than young persons, and we find from Mr. Wainwright that fungus in the cornea of the eye mostly affects persons under twenty years of age, it is infinitely certain that most of the cases of fungus reported to be caused by the eye, were in fact the equally terrible disease now passing under consideration. According to Mr. Thwaites, the only source of the external or appendageous fungus to be primarily attacked by carcinoma is the sclerotic gland, conjunctiva, and eyelids; while the evidence of many cases has assured him, that fungus hematodes may originate in any portion of the eye, with the exception of the iris and ciliary bodies of the interior of the eye, p. 295 (not and 421). This account, however, differs from that advanced by Mr. Wainwright and Professor Scarpa, who describe the disease as first commencing in the iris, and particularly at the point where the aqueous humor enters the eye. "For (says the latter author, in the first appearance of the infection) a greenish spot, the centre, on examination, is found to be purplish red, and, in other words, to have degenerated into the so-called fungus. It is also found, that this disease spreads, while the fungus hematodes is in its incipient state, does not appear to have suffered any remarkable alteration in its nature, and that it is only at a more advanced period of the disease that this membrane becomes thickened and organized with its connection with the sclerotic." The disease continues, even in the most advanced stage of the disease, preserves, more than all others, its natural form. (On the Principal Diseases of the Eye, p. 307, ed. 2.) In cases of fungus hematodes, the sight of seeing objects is generally destroyed before the direction of pupils is turned to the outward. Frequently, however, a slow, dimmed, or aphakic, precedes the growth of the disease. When no external evidence has occurred, the first symptom is a trivial itching at the vertex of the cornea, the iris becoming, at the same time, extremely vascular, and altered in colour, and the pupil dilated and irritable. There is seldom much vascular matter in the eye; but the iris is sometimes observed to be enlarged and to extend. In adults, fungus hematodes of the eye occasionally commences without any apparent cause, though sometimes it is consequent on a blow. At first, the iris cornea is slightly reddened, and vision imperfect. The iris and cornea, or slight increase of vision, and an opening of the pupil is experienced; the eye itches, and the iris is changed.

With regard to the state of the fungus hematodes of the eye, the only chance of effective treatment depends upon the early recognition of the disease. It is not to be acknowledged, however, that most of the operations, in which the diseased eye has been removed, have been proved unsuccessful, owing to a recurrence of the disease. The removal of such a success may be expected to the optic nerve and other parts being almost always in a morbid state, before all attempts to retain the eye. One case, however, detailed by Mr. Thompson (who has sent in the following letter concerning the operation for the disease, was operated upon, and as a consequence of the disease had occurred a remarkable improvement. No other instance was alluded to more than the congenital and extent of the disease reported.—On the Principal Diseases of the Eye, p. 412.) The most successful extirpation of an eye in its advanced stage of this disease, and, perhaps, the only satisfactory one at present on record, is that which was performed by Mr. Wainwright, the case containing complete details of the operation.—*Opus Oculi*, Mr. Wainwright, vol. II, p. 411. The operation was nearly always found to be successful, when the disease was advanced so far that the posterior chamber is filled by the fungus mass. With the very few exceptions, which there are to this statement, it may be correctly said, that, as no internal preparation was attempted, certainly affected the heart, hope of curing any case of the fungus hematodes, it is manifest, that when the disease of the eye extends beyond the limits of any internal

aid from surgery. In a case which I saw in April, 1821, in the London Eye Infirmary, the disease formed a fungus mass as large as an orange, accompanied with enlarged lymphatic glands over the tumor. The patient was an infant. In this instance, Mr. Lawrence used, as a local application, the liquor oculi sedentaria, prepared by Mr. Bailey, which was found to lessen considerably the child's suffering.—(See particularly Wainwright's *On the Principal Diseases of the Eye*, vol. II, p. 412, and in *Wainwright's Treatise on Diseases of the Eye*, and Dr. Treves's *Synopsis of the Diseases of the Eye*, 8vo. Lond. 1823.)

STAGES OF THE DISEASE OF THE EYE

1. In the extension, the disease begins with a small cauliflower growth, which, moist and elastic, it flows to the touch, relieving even, such as a tumor; but otherwise it is firm. At first, it arises from the cornea, but by degrees a second tumor grows successively through it more and more frequently, and at length becomes incessant. For a considerable time the tumor is smooth and even; but afterwards it projects irregularly at one or more points, and the skin at these places becomes of a whitish color, and feels thicker. At this situation, it easily yields to pressure, but instantly rises up again. Small openings now form in these projections, through which is discharged a thin bloody matter. Almost immediately after these fissures burst, a small fungus protrudes from the pupil, and then rapidly increases, both in breadth and height, and has exactly the appearance of a cauliflower fungus, and frequently bleeds profusely. The matter is thin, and exceedingly soft, and the pain becomes of the stinging kind. The instruments, by a little way round these tumors, are not to be used. After treatment takes place, the neighbouring glands swell, and assume exactly the same condition as the primary tumor. If the patient will submit the disease to its present advanced progress, similar tumors form in other parts of the body, and the patient dies soon.

After death or preparation the tumor is found to consist of a soft substance, sometimes like the basis of a greyish tumor, and greatly appearance, with this membranous structure, extending through it, and ends, or absorption in different places, occupying a thin fleshy matter, occasionally in very considerable quantity. There does not seem to be any entire rest, extending the tumor. It is very frequently seen to grow between the eyelids, or even to the lower, to which it often appears to adhere. The neighbouring structures are of a yellow color, and lose their former appearance, becoming more like liver than vessels. The tumor is always cancerous in the vicinity of the disease.

The disease is sometimes caused by external violence, though it is general there is no evident cause whatever.—(Observations on Inflammation, by J. Hunter, vol. 2.)

Mr. Hay has given several cases of the fungus hematodes. If I have the most particular circumstances relative to one of them, it will suffice to inform the reader of the facts in which this terrible affection has presented itself in this gentleman's practice.

A young man, David Macgregor, two years before applying to Mr. Hay, perceived a small swelling on the inner of his right eye, but far from the pupil. This tumor was movable, and did not impede the motion of the eye; it was not discoloured, but was painful when moved or pressed upon. It continued in this state half a year, and then the man having been his knee against a stone it gradually increased in bulk, but did not exceed the size of an egg. The skin was now discoloured with blue spots, which were taken to be veins. He could still walk with ease, and follow his business.

Two months before his admission into the London Infirmary he was with a fall, and violently beat his knee, but did not strike it against any thing. The tumor began immediately to enlarge; and, within a few days, it reached half way up the inside of the thigh. About a fortnight after this accident the skin burst at the lowest part of the tumor, and discharged some blood. A dark-colored fungus, about the size of a pigeon's egg, here made its appearance, and a few weeks afterwards the skin burst at another part of the large tumor, and some blood was again discharged. From the latter arose another fungus, which had increased in the

In short, the only chance of cure consists in destroying the whole of the diseased parts, restoring not only the wall, but the fungus membrane, but every part of the cyst, more or less, in which it may be contained. An incision of this kind, however, is only advisable in the early stages, while the disease is entirely local, if a severe case, a considerable part to be destroyed; for, after the neighbouring glands have become affected, the chance of recovery is almost destroyed. It is sometimes difficult, however, to perform patients at an early period in relation to prognosis or prognosis, because the pain and inflammation are considerable; and the operation should be timed with all the views which a restoration of its absolute necessity and the fatal point of duty ought to bear.

The attempts to cure the disease by setting it away, have been attended with such ill success that some surgeons deem it advisable not to follow this method, but to destroy the bulk of the cyst. The principal views of the disease appear to me to be most judicious and rational. First, that if an incision be made to cut every the cyst, and save the wall, the surgeon must be careful to remove at the same time a considerable quantity of the soft parts in the neighbourhood of the swelling, so that the matter that is about the cyst is likely to be removed. Thirdly, that after the incision is made, an absolute examination of the surface of the wound should be made, and every dangerous part should be cut away. Fourthly, that should the disease still remain, the operation ought to be judiciously performed. Fifthly, that should the disease never be applied to this disease. Finally, that even when one of these operations effectively removes the disease of the wall, the patient's entire recovery is always benefited accordingly to the views of the disease, and other possible parts being properly affected, at the time of the operation, with the whole set of disease.

SYMPTOMS OF THE DISEASE.

1. Fungus humoralis of the testis sometimes begins in its glandular part, sometimes in the epididymis. Its progress is slow, and the pain generally not severe. But as soon as there is any complaint of hardness of the diseased part, or change in the colour. When the testis has become considerably large, it feels remarkably soft and elastic, as if it contained a fluid. Hence, the case has often been mistaken for a hydrocele, and sometimes with a success. (Wadding, *Edin. Med. Chir. Trans.* vol. 2, p. 38.) Occasionally, when the tumour is large, it is in some places hard, in others soft. The hardness may be known by the nature beginning to collect at the bottom of the scrotum, and then ascending towards the spermatic cord, and by the swelling being diminished towards the tubercle. When the fungus humoralis begins with a general enlargement of the entire testis, followed by a hollow, which extends to the epididymis. It is not in the distended disease of the testis, and is much harder than a simple bulk of water. (Roth, *ibid.*) As the disease advances, the testis becomes more and more enlarged, but not so much as the epididymis. When the ligament glandularis becomes enlarged, they often become of enormous size; and as soon as the epididymis then follows, large portions of them slowly away. Fungus humoralis of the testis is seldom attended with more distress than old age. The disease, the exhibition of the diseased testis is found to present a nodular or pimple appearance, generally of a pale brownish colour, though sometimes red. It is joined near the tunica vaginalis and tunica albuginea are adherent together occasionally, in fact between them.

In an example described by Mr. Lawrence, the swelling of the testis consisted of cellular matter filled with pimple matter. Numerous tubercles of the disease were found in the scrotum, and along the penis, intermingled with cellular matter. A mass of soft matter, which it was a man's kindness to the spine behind the scrotum and penis, which felt very hard and elastic for some time. The spermatic vessels could not be found. (See *Med. Chir. Trans.* vol. 4, p. 11.)

The only chance of a cure must be formed from a very early performance of castration, before the disease is extended to the inguinal glands, or up to the spermatic cord. Indeed, very little hope should be

placed in the removal of the tumour; the fungus humoralis appears to be rather a constitutional than a local disease. Nearly every case on record has terminated fatally, and upon dissection shows the liver, the lungs, the brain, the mesenteric glands, or other internal parts, have been found affected with the same disease. In one case described by Mr. Lawrence, tubercles of a cellular structure to the disease in the testis were found in the lungs, liver, and, in short, in nearly all the thoracic and abdominal viscera, though the contents of the skull were free from disease. (See *Chir. Trans.* vol. 4, p. 11.)

Who shall give this subject with strong words of the principal differences between two diseases which have been commonly mistaken. A scirrhus testis is, from the commonest, hard, firm, and homogeneous, and is composed of two substances, one hardened and fibrous, the other soft and mucous. The fibrous matter is the most abundant, consisting of cells, which are fewer than the soft substance between them. A scirrhus testis, caused in the gland is not equalled by any separated from the latter part, so much as the two substances blended. A scirrhus is a further situation sometimes involves the surrounding cellular substance, so as to form a kind of cystic, and becomes a circumscribed tumour. When a scirrhus involves the testis, a thin scar is described, and a good deal of the hard fibrous substance is destroyed by the absorption; some parts become affected, and the patient dies from the increased pressure of the disease, and the retention of the secretion. Sometimes, though not always, after a scirrhus has developed, it ends in fungus of a very hard texture. Such excruciating, however, is not met described by the physicians. Cancerous nodes, also, frequently put on for a short time, in some cases, an appearance of fluctuation. On the other hand, the fungus humoralis, while of moderate size, is soft, elastic swelling, with an equal surface, and a decided feel of fluctuation. It is a general, upon examination, being involved within a capsule. The substance of the tumour, instead of being for the most part hard, consists of a soft, pulpy, medullary matter, which usually flows with water. When liberation occurs, the cancer is not increased by this process, which scirrhus; but a fungus is created, and the whole swelling grows with increased rapidity. Cancerous diseases are mostly met with in persons of advanced age, while fungus humoralis generally affects young subjects. (Wadding.) Many surgeons have now proved, that the substance of fungus humoralis may contain cellular matter, which is the only cellular matter.

Fungus humoralis, in its early stage, is generally attended with less pain than what is experienced in cancer of scirrhus. The former also has a less definite boundary than a scirrhus, and it is more difficult to say where the diseased structure terminates, and where the healthy commences. When the disease is in the breast, there is less tendency than in scirrhus to increase in the cellular glands, which may require some thought the disorder in the breast may have advanced to suppuration and necrosis. In the breast the disease is also much quicker in its progress than scirrhus. (See *Chir. Trans.* vol. 2, p. 38.)

In cases of external cancer, the vessels are in general affected at the same time with scirrhus disease, but the similarity of examples of fungus humoralis, this disease is found affecting in the same subject a variety of parts. In addition to the external tumour, we find swellings of a similar nature, perhaps, in the liver, the lungs, the mesenteric glands, or even in the brain. Yet Mr. Ross will have it, that cancer and fungus humoralis are the same disease; or at least that the latter is only a species of the former, and that in both cases disease proper to the testis prevails. (See *Chir. Trans.* vol. 4, p. 11.)

See *Observations on Inflammation*, by J. Brown, vol. 2. *Key's Practical Observations on Surgery*, vol. 2. *First and Second Editions*. *Observations on Fungus Humoralis*, as Soft Cancer, by James Wardrop, M.D. Edin. 1808. This last publication is highly interesting to the attention of the surgical practitioner, the disease in different organs being well described, and the characters distinctly marked from that of cancer.

A note of this disease is related to vol. 5 of the *Lancet*.

the Medical Journal. It was the consequence of an attempt to cure a gonorrhoea by means of a lotion, and it proved fatal. A case is also related by Dr. Abernethy, in *Surgical Observations*, 1804, p. 93. See also a Case of Dissected Testicle, accompanied with Abscess of the Lung and Pleura, by H. Esdaile, in *Medical-Chirurg. Trans.* vol. 2, p. 53, &c. in which not, four other cases are recorded by Dr. Latham, p. 71, et seq., and one by Dr. Longstaffe, p. 277, which last Latham is here quoted as occurring with the gonorrhoea and Dr. Latham, a short time before the patient died. See also Longstaffe's *Cases and Observations* in the 5th and 6th vols. of the same work. Former fell a Londoner in 1814; on *Parasitic &c. in the Cervix Uteri*, in *Chirurg. Transactions*, p. 211, &c. On *Foreign Matter in the Cervix Uteri* see some valuable observations in the 4th edition of *Wegscheide's Treatise on the Diseases of the Uterus*. See also *Reynolds on Diseases of the Uterus*, and *Thomson's Synopsis of Diseases of the Uterus*, 2nd. Lond. 1831. C. Fick on *Diseases of the Eye*, p. 267, ed. by Welford, 2nd. Lond. 1855.

Respecting mediastary carcinoma, which is generally considered the more efficacious as far as immatures, more further observation will be bestowed in the article Tumours.

PERUNCULUS. (From *peru*, see page.) A boil, so named from the violence of the heat and inflammation attending it.

A boil is a well-circumscribed, very protruded, hard, deep red, inflammatory swelling, which is extremely painful, and commonly terminates in a slow and protracted suppuration. The focus of the tumour is generally that of a boil, the size of which is considerably below the surface. Upon the apex elevated part of the boil there is usually a whitish or livid point, which is insignificantly scabbed, and immediately beneath this is the point of the abscess. The matter is usually more or less, is always very abundant, and never finally in firm, sanguineous, rounded, white, blood. The organ is not less attacked with fever, except when the tumour is very large, situated in a sensitive part, or when several of these swellings occur at the same time in different places. In the late circumstances they often occasion in children, and even in infants' whites, tenderness, loss of appetite, sweating &c. They rarely exceed a pigeon's egg in size, and they may originate in any part of the body.

Boils commonly arise from constitutional causes. Young persons, and especially subjects of full plethoric habit, are most subject to them. The disease is also observed to occur with most frequency in the spring. — (*Lancet*, Pathologic. Chir. t. 1, p. 163.) According to Richardson, the origin of this depends upon a disordered state of the gastric organs. — (*Neurologie Chir.* t. 1, p. 124, &c. 2.) Frequently they arise without any evident cause, and especially in healthy constitutions. At other times they follow eruptive diseases and typhus. — (*W. Gibson, Lectures, &c. of Surgery*, p. 48, vol. 1.)

The suppuration attending a boil is never perfect, and the matter which issues is not only mixed with blood, but accompanied with a bloody exudation, which issue generally is discharged before the part affected well separate kindly, and the disease end. Richer compares the stage is a kind of bag or cyst, and the whole boil is an inflamed cystic tumour.

The best plan is mostly to endeavour to make this suppurate as freely as possible by applying external caustic remedies. This seems to be the natural course of the disease in its progress to a cure, and indeed, all endeavours to disperse inflammation promote

excessively full, or succeed very imperfectly; only removing the inflammation, and leaving behind an indurated hardiness, which sometimes varies in persistence, according to its situation, every now and then returns anew, and never entirely disappears until a new suppuration has been established.

In a very few cases, perhaps, a cure is to be ascribed to various views. For this purpose, besides bleeding, gentle bruciations, and a low diet, which are requisite in this as well as other local inflammations, some prescribe an external application freely brought on, diluted with sulphuric acid, diluted, or concentrated oil.

But in the majority of instances suppuration must be prevented by the use of emollient poultices. The incision, when allowed to issue, generally does so in 10 or 12 days. However, as the suppurate is generally long in forming, and too slow to allow the sloughy exudate substance to be discharged, it is always best, as soon as matter is known to exist in the tumour, to make a free opening with a lancet, and immediately afterwards to press out as much of the matter and blood as can be gradually done. This having been accomplished, and the rest of the slough pressed out as soon as it is practicable, healthy pus will be issued, and the part will gradually subside. Until the suppurate becomes of the healthy kind, and the sloughy substance is completely discharged, an emollient dressed poultice is a good application; and when granulations have begun to fill up the cavity, pain less, and a larger poultice by its better cleansing necessary.

For the purpose of stimulating the parts, and curing it to fill up, *Paracelsus* Gilman, of Tyndall, the surgeon employed with various success in the cure of boils.

When there is reason to suppose the parts ought to be in a disordered state, an emollient is given in the early part of the treatment, and afterward repeated doses of any of the mild purgatives.

When an indurated tubercle continues after suppuration, and suppurative state of long has terminated, the part should be rubbed with compressed mercurial ointment.

Besides the above accidents, authors describe a variety of one, which is not frequently as large as a walnut, and which is diffused slowly from the surface, sometimes vesicular, sometimes, and in most instances which have been figured by the use of mercury.

The syphilitic boil is commonly pointed upon the extremities, is of the same size as the syphilitic boil, but is not attended with much pain, nor any considerable discolouration of the skin, and suppuration is not advanced, and the matter is seldom ever formed before the end of three or four weeks. Thus, like the former, sometimes appears in a considerable number at a time. The discharge is always thicker than pus, and when the boil is large, and has been long in separating, a great deal of strongly odorous matter must be got off before the cure will hold.

The principal thing requisite in the local treatment of all tubercles and tubercular tumours is to make an early free opening into them, and to pour on the matter and sloughs, employing excellent poultices, all the method parts are detached and removed, and afterward simple dressings. — (*See Principles of Surgery*, Book II, *Suppurative &c. of Wounds*, &c. *Lancet*, Pathologic. Chir. t. 1, p. 12. Richardson, *Neurologie Chir.* t. 1, p. 122, &c. V. W. Gibson's *Lectures of Surgery*, vol. 1, *Paracelsus* 1801. C. F. H. Larrey's *Recherches*, &c. t. 1, p. 257, &c. 1822. *N. J. Chalmers, Researches for Chir.* t. 1, p. 24, &c. 1823.)

G

GANGLION. (*ganglion*.) Is surgery, a tumour on a tendon or aponeurosis.

A ganglion is an outpocket, circumscribed, suppurative swelling, commonly free from pain, resting on a fibrous in the colour of the skin, and formed upon tendons in different parts of the body, but most frequently upon the back of the hand and over the wrist. A French gentleman consulted me, who had one upon the upper part of his foot, which created a great sensation of

weakness in the motion of the foot; and I have twice since that ganglion, which particularly affects the foot, how the knee-joint is to be made who are in the habit of having a great deal in order to move some. A curious example is recorded, in which a ganglion, situated exactly over the spinal column, and the spinal cord itself, was at first supposed to be an aneurysm. — (*See Folia Med. and Surg. Journ.* No. April, 1811.) These tumours, when occupied, often in passing

considerable elasticity. They often never approached by any accident; frequently, they are the consequence of bruises and violent agitations. They seldom attain a considerable size, and ordinarily are not painful, though every now and then there are instances to the contrary. When opened, they are found to be filled with a viscid, transparent fluid, resembling white of egg. If they do not disappear of themselves, or are not cured while seated by surgical means, they, in some cases, become so large that they cause great inconvenience, by obstructing the motion of the part and interfering it partly.

Dissecting applications sometimes succeed in curing ganglions, and in this country itself with the oleum serpentis is a very common method. There, when even such remedies very much benefited by this plan of treatment, but seldom cured; for no sooner has the fluid evacuated than the fluid is the cyst is general, and sometimes again.

Compressions are usually recommended than dissection. Persons with ganglions have been recommended to rub them strongly with their thumb several times a day. After they had been opened very often the tumor has sometimes disappeared. But the best method is to make constant pressure or compresses by means of a piece of sheet-lead, bound upon the part with a bandage. There is no objection, however, in taking care as before a day, in conjunction with this treatment, frictions with the oleum serpentis or diaphanized mineral oil, provided these frictions together do not seem likely to make the tumor increase, as even slight motion always so carefully avoided. Ganglions, when injured too much, have been known to become about malignant fungous diseases.

Scars have been recommended to be introduced through ganglions with a view of curing them. This method, however, is not an eligible one; for it is by its effects free from danger, as the records of surgery fully prove. Carcinomata, and even a malignant testis (Med. Journ. vol. 5), have arisen from the irritation of a wound passed through a ganglion.

Frequently, when a ganglion inflamed and abscesses, the cyst throws out a fungus which is of a very malignant nature. Hence, the practitioner should avoid making an opening into the cyst, or doing any thing which is likely to excite suppuration or inflammation of the disease. Ganglions may be cured by pressure sufficient to rupture the cyst, and some authors have recommended putting the hand affected upon a table, and then striking the ganglion several times with the fist or a mallet. The cyst of a recent ganglion may also be burst by compressing it strongly with the thumb, or with the intervention of a piece of tannin; the fluid effused into the adjacent cellular membrane, and pressure being now relaxed, the opposite side of the cavity become filled by the exuberant inflammation, and the recurrence of the disease is prevented. On this principle Mr. Acland Cooper cures the disease. (See *Encyclopædia Medico-chir.* part. 4th art. Ganglion, London, Publishers. Chir. t. 1, p. 40, 41; *Medic. Novæque Practicæ Chir.* t. 2, p. 1.)

In almost every instance, a ganglion may be cured by pressure and friction; and if not actually cured, the disease may be rendered so harmless by these means, that few patients would choose to have the tumor cut out. These frictions, the swelling becomes very much diminished, and should it enlarge again, the mode of cure is the same, and the case so little troublesome, that patients generally content themselves with occasionally wearing a piece of lead on the part.

But when ganglions resist all attempts to disperse or reduce them, when they become extremely numerous, either by obstructing the motions of the part or causing pain, they should be carefully dissected out by first making a longitudinal incision in the skin covering them, then separating the cyst opening side from the contiguous parts, and finally cutting every particle of it off the subjacent tendon or fascia. The greatest care must be taken not to injure any opening in the cyst, as to let out the contents, and make it collapse; a consequence which would render the dissection of it entirely out much more difficult.

The operation being accomplished, the skin is to be brought together with sticking plaster, and a compress placed over the situation of the tumor, with a view of healing the wound and the cavity is obliterated.

When the ganglion has burst, or is situated, it is best to remove the diseased skin together with the cyst,

and of course the incision made by oval or circular, as may seem most convenient. The grand object is, not to allow any particle of the cyst to remain behind, as it would be very likely to throw out a fungus, and produce a cure. In Warton's Cases of Surgery is an account of two considerable ganglions which this treatment, in imitation of Celsus and Ponsus Agrippa, thought it right to extirpate. These had become adherent to the fibres of the fingers. In the operation he was obliged to cut the transverse ligament of the wrist, and the patient, who before could not shut their hands, now close their fingers, perfectly regained the use of these parts. Mr. Gooch relates a case of the same kind, which had been occasioned by a violent bruise three or four years before. The tumor rubbed from the wrist to the cubit of the hand, and created a great deal of pain. Mr. Gooch separated it, and then removed the portion of the hand and fore-riding of the joint by the use of trepanning application and various phlebotomy, made with a machine constructed for the purpose. Other cases, confirming the safety of curing ganglions are recorded in the London Medical Journal for 1807, p. 121; by Ellis, in *Ann. de Med. et Chirurgie de Paris*, t. 5, page 150; Schenker, in *Chir. Hædelsburger*, t. 1, p. 232; *Journal, Lippincott*.

The ganglions which occur just before the knee I have seen cured by a little tannin applied over them, and kept open by the same means. Ganglions, indeed, have been proposed as a means of discharging other ganglions. (Lange, *Chir. Chir.* t. 2, p. 5.)

For information relative to ganglions, consult Warton's Cases in Surgery, *Classical Works of E. Gooch*, vol. 2, p. 216, *Master's Surgery*, R. Acland's Surgery, *Letter's Synopsis of Surgery*, *Encyclopædia Medico-chir.* part. 4th art. Ganglion. *Pract. Chir.* for Wundt, t. 1, p. 40, 41; *Journal Pathologie* (Chir. t. 1, p. 260). *Dict. des Sciences Méd.* t. 17, p. 211.

GANGRENE. (From *γὰρ* to feed upon.) An insupportable mortification, so named from its eating away the flesh.

Authors have generally distinguished mortification into two stages, the first, or isempic, and the second, or ischæmic, which is attended with a sudden discoloration of the part, which after being yellowish, becomes of a greenish hue, a detachment of the cuticle, under which a fetid fluid is effused; lastly, the swelling, tension, and hardness of the part, the inflammation subsides, and on separating the part a cavity is perceptible, owing to the excretion of air in the gangrenous parts.

When the part has become quite cold, black, stony, insupportable to moving, and destitute of all feeling, circulation, and life, this is the second stage of mortification, termed sphacelus. Gangrene, however, is frequently met with gradually with the word mortification. (See *Mortification*.)

GASTROICILE. (From *γαστήρ*, the stomach, and *κύλινδρος*, a ferment.) A ferment of the stomach.

GASTROGRAPHIA, or gastrography. (From *γαστήρ*, the belly, and *γράφω*, to write.) A state of the belly, and sense of its contents.

Although the term *gastrographia*, is strictness of style, signifies the sewing up of any wound of the belly, yet Mr. W. Sharp informs us that in his time the word signified, that the wound of the abdomen was completed with another of the bowels.

The moderns, I think, seem to fix the meaning of the word to the operation of sewing up a wound in the peritoneum of the abdomen.

What was formerly meant by *gastrographia* could scarcely ever be practised, because the symptoms laid down for distinguishing when an intestine is wounded do not, with any certainly determine in what particular part it is wounded; which want of information makes it, almost to open the abdomen in order to get at it. Hence the operation of stitching the bowels can only take place when they fall out of the abdomen, and when we can see where the wound is situated. And, indeed, even in these circumstances the employment of sutures is a practice the propriety of which is questionable, as will be further considered in the article *Wound*.

The circumstances making the practice of sewing up a wounded intestine proper are such, that Blandin, who was the most famous surgeon in the French army a great many years, and at a period when deaths were particularly frequent, and his country at war, declared

giving internally the extract of croak, relieved, and scap. — (*Engelhardt's Mythologie, p. 101.*) The topical use of stilly ought to be tried, but from the history of the disease, the chance of cure here, evidently be nearly hopeless. — (See also *Dr. B. Reprint de Morbis Internis, Paris, 4to, 1800.*)

GLIST. By this word is commonly understood a convulsed running or discharge, after the inflammatory symptoms it has had for some time ceased, attended with pain, sometimes making water, &c. Mr. Hunter remarks, that it differs from a gonorrhoea in being spontaneous, and in the discharge consisting of globular bodies, contained in a stony matrix instead of serum. He says, that a gleet seems to take its rise from a kind of action which the parts have contracted. The disease, however, sometimes stops of itself, even after every method has been imperfectly tried. This probably depends upon accidental changes in the constitution, and not at all upon the nature of the inflammation. Mr. Hunter had a suspicion that some gleet were connected with aphrodisia. Certain it is, the venereal cases more gleet than the common cold bath, or any other mode of bathing; and a cure was sometimes effected, although he was accompanied by an epidemic of dried sea-water.

Gleets are often attended with a venereal constitution. They also sometimes arise from other affections of the urinary, besides gonorrhoea. A cure is almost always accompanied with a gleet, and so constitutes a disease of the venereal gland.

It is remarked by Mr. Hunter, that if a gonorrhoea not arise from any venereal cause, and cannot be supposed to be a return of a former gleet, its consequence of a gonorrhoea, after a situation or disordered prostate gland is to be suspected; an inquiry should be made whether the stream of urine is meeting this condition, whether there is any difficulty in voiding it, and why; then the truth is made a little frequent. It should be by each symptom, a leucorrhoea, either under the common name, should be introduced; and if a gleet (as the English with complete ease, the French is probably in the prostate gland, which should not be mistaken. — (*See, however, Struthers's, and Whistler's Works.*)

Exhaustion, impotency, and the venereal cure, given internally, are of service. Especially in slight cases; and when they are useful they prove so almost immediately. Hence, if they had neither answered nor improved the gleet in five or six days, Mr. Hunter never employed these things. The same observation applies to leucorrhoea, as celebrated of late as a remedy for gonorrhoea and gleet, and the common dose of which is ʒi. Every case does not last these seven days. As the discharge when removed is also apt to recur, such medicine should be continued for some time after the symptoms have disappeared.

When the whole constitution is weak, the cold bath, sea-bath, bark, and steel may be given. The diet should consist of milk and stilt of steel, given as internal stimulants, have little power.

With regard to local applications, the uterine pessaries recently used are, the decoction of bark, sulphur of zinc, stann, and preparations of lead. The silver vitellina species, of the old London Dispensatory, diluted with eight times its quantity of water, makes a very good injection.

Invigorating applications consist either of injections or bougies, usually accompanied with irritating cathartics. Various remedies may be considered as having the same effect. Such applications should never be used till the other methods have been fully used and failed, unavailing. Only at first increase the discharge, and as this secret is somewhat stopped, the cure. Two grains of the oxydum of mercury, dissolved in eight ounces of distilled water, make a very good irritating injection. In venereal leucorrhoea, as applications may be given here, and therefore, if possible, the possibility of the parts to bear its employment should first be made out.

Bougies sometimes are violent, but Mr. Hunter thought, that most efficacious these injections. A bougie introduced six or seven times, and that he used a month or six weeks before the cure can be depended upon. Bougies introduced with sulphur or turpentine were formerly employed for the cure of gleet; they did not require so long a trial as venereal bougies: at present, I believe, they are not used at all by any surgeon of eminence. Venereal bougies are employed should be under the common use.

Mr. Hunter knew a gleet disappear on the smoking of one or two ounces of the opium. Gleet here also been cured by a blister, put the under side of the scrotum, and by electricity.

In every plan of treatment, rest or quietness is generally of great consequence; but, after the failure of the local means, riding on horseback will sometimes immediately effect a cure.

Regularity and moderation in diet are to be observed. Abstinence with women often causes a return or increase of gleet; and in each case, it gives symptoms of a fresh infection; but the difference between this and a gonorrhoea is, that here the return is almost immediately after the cure.

Gleets in women are cured easily in the same manner as those of men. Turpentine, however, has no specific effect on the vagina, and the strongest injections used, may also be stronger than those intended for male patients.

The history of gonorrhoea, pretty freely described, and for some time, a powerful means of restoring the tone of the genital organs, and of restoring them. The use, however, must be preceded by some time. In most instances of the system in which a gleet discharge depends upon a venereal cause in the prostate gland, Dr. Ferrius, of New-York, has given the powdered extract of gold with milk, in cases where the essential function of urine proved irritable, and seemed to require constant use. One Atomized remedy, the specific, originated in increases of the secret to be overlooked. While it is necessary, the tone of the genital organs, it is valuable in various affections of the urinary organs. — (*See, p.*

See A Treatise on the Venereal Disease, by John Hunter, M.D. Also, Nodding's Practical Therapeutics, Venereal Complications.

GLAUCOCATHESIS. (*From glaucos, the green, and cathesis, to remove.*) The green glaucocathesis was a sort of leucorrhoea, one of the kinds of which served to depress the lungs, while the other was applied under the skin.

COITUS. See *Beauchamp's*.

GYNOECOLOGIA. (*From gyna, the woman, and logos, to talk.*) Etymologically, an imaginary knowledge of the female sex; but, according to modern usage, a disordered genital infectious matter, from the first in the male, and from the vagina and uterus of the female, whence it is called, &c., in the female subject.

Dr. Stenhouse, after considering the etymological import of the word, remarks, that if a Greek word is to be translated, he would call it *leucorrhoea*, *leucorrhoea*, *leucorrhoea*, and *leucorrhoea*. However, as most of the moderns consider the discharge as just, not merely, the etymological import of *leucorrhoea* is as objectionable as that of *gonorrhoea*. Mr. Hunter has repeatedly examined the discharge with a microscope, but without perceiving any essential difference between such discharge and the pus effused from an ulcer. — (*See Complications affecting the Scrotum and Ejaculation of the Penis, p. 208.*) In English, the disease is sometimes called a *drop*, from the old French word *droppe*, which were vulgar slang, kept and imbibed by stage prostitutes, and generally confined to a particular quarter of the town, so as even now the case is as frequent as the great town in Italy. In German, the disease is called a *trapper*, from *trappen*, and in French, a *leucorrhoea*, from *leucos* and *trapping* in making water. (*See Hunter's*)

We shall first discuss the matter with regard to Mr. Hunter's opinions concerning the nature of gonorrhoea, its symptoms, and treatment; and, lastly, take notice of the observations of some other writers.

When an irritating matter of any kind is applied to a sensitive part, it increases that secretion, and changes it from its natural state to some other. In the present instance, it is changed from serum to pus.

Till about the year 1750, it was generally supposed, that the matter from the urethra in cases of gonorrhoea arose from blood in the passages; but about that time it was ascertained that pus might be secreted without a breach of continuity. It was first accidentally proved by dissection, that pus might be formed in the bag of the pleura without absorption; and Mr. Hunter afterwards examined the urethra of male patients and others, who were diseased or died while known to be affected with gonorrhoea, and demonstrated that the canal was merely free from every appearance of blood.

The time when gonorrhoea first appears after intercourse

tion, is extremely various. It generally comes on sooner than a chancre. Mr. Hunter has reason to believe that in some instances the disease begins in a few hours; while in others, six weeks previously elapsed; but he has known it begin at all the intermediate periods. However, it was his opinion, that about six, eight, ten, or twelve days after infection is the most common period.

The nature of the urethra is subject to inflammation and suppuration often varies with respect to the various parts; and sometimes discharges impudently, when the immediate cause has been removed. Such may be called early gonorrhoea, having nothing of the venereal infection in them.

Mr. Hunter knew of cases in which the urethra suppurated, with the emission of a fluid, and all the symptoms of a gonorrhoea were produced. This happened directly from the same patient. The urethra is known to be sometimes the seat of the gleet; and Mr. Hunter was acquainted with instances of its being the seat of venereal infection.

When a morbid matter has once entered the inflamed urethra, its secretions are increased and viscid almost. Also, when irritation has produced in the urethra, just as it does in the gland, a secretion of mucus takes place, the infection of which, it is said, seems to be confined to the inflamed part. But in inflammation arising from specific or venereal poisons, the infection cannot be thus got rid of; for although the first irritating matter be washed away, yet the new matter has the same quality as the original one; and therefore, upon the same principle, it would produce a perpetuation of inflammation, even if the venereal infection, like many other specific diseases, were not what it really is, kept up by the specific quality of the inflammation itself. This inflammation, however, is highly capable of cure, as I have said, the symptoms peculiar to it, consisting of suppuration, by the parts becoming less and less susceptible of irritation; and the subsequent external application has no power of removing the original irritation, for otherwise there would be no need to discharge. The time when the susceptibility of the urethra lasts varies almost upon the difference in the constitution, and not upon any difference in the poison itself.

Mr. Hunter believed that the venereal disease only caused spontaneously when it attacked a secreting surface, and produced a more secretion of pus without suppuration. Such were some of the arguments of this great man, who was a firm believer in the identity of the poisons of syphilis and gonorrhoea: but this idea, and the hypothesis about the impossibility of any spontaneous cure of venereal sores, are now very generally relinquished.

The first symptoms of gonorrhoea is generally an itching at the neck of the urethra, sometimes extending over the whole gland. A little itching of the lips of the urethra, the effect of inflammation, is next observable, and soon afterwards a running appears.

The itching changes into pain, more particularly at the time of voiding the urine. There is often no pain till some time after the appearance of the discharge and other symptoms; and in early gonorrhoea there is hardly any pain at all even when the discharge is very considerable. At other times, a great degree of soreness extends long before any discharge appears. There is generally a particular soreness in the penis, and more especially in the glans. The glans has also a kind of asperity, especially near the beginning of the urethra, where the skin, being dissipated, searred, and red, resembles in appearance the mouth of the urethra is, in every situation, redly inflamed. The surface of the glans itself is often in a half-suppurated state, consequently very tender; and it secretes a sort of discharge. Venereal infection is likewise glaucous, which is known by the stream of urine being purpler than common. This proceeds from the fluid of the penis in general, and either from the lining of the urethra being inflamed, or in a venereal state. The heat of the patient while voiding the urine, when disposed the urethra in contrast, and the stream of urine is generally much heated and broken as soon as it leaves the passage. There is frequently some degree of hæmorrhage from the urethra, perhaps from the defect on the membrane, more especially when there is a discharge, or a tendency to it. Small swellings often occur along the inner surface of the penis,

in the course of the urination. These Mr. Hunter ascribed to be enlarged glands of the passage. They are constantly suppurated and larvee extremely, but are confined to the urethra itself. Mr. Hunter has also supposed such eruptions to be due to the venereal virus, glands of the urethra themselves with venereal infection of the parts of the duct being closed, in a venereal manner to what happens in the duct leading from the lacteal sac to the testis, and so on to induce inflammation, suppuration, and abscesses. Hemorrhage and swelling may also occur in the dilation of the penile glands, and end in considerable abscesses in the perineum. This latter abscess is best treated internally or externally, and sometimes in both ways, as in a gonorrhoea female is perineum.

A sinus is often left all along the inner side of the penis, frequently extending as far as the anus. The sinus is particularly great in children; but the same differs from children by the penis following straight. In most cases of gonorrhoea, external abscesses and even sometimes fistulas to the testis, are sometimes of great service. Mr. Hunter thought that they were formed to suppose them of venereal origin.

The natural history descends from the glands of the urethra is first changed from a dry, transparent, watery secretion to a viscid, whitish fluid; and the burning heat which the passage naturally retains becomes less transparent; with these symptoms, however, are usually the pain, burning, more and more the quantity of common pus.

The matter of gonorrhoea often has a peculiar color and consistency, sometimes from a virus in a pure, and often to a great extent. These changes depend on the increase and decrease of the inflammation, and on the poisonous quality of the matter itself; for an irritation of these parts, equal to that produced in gonorrhoea, will produce the same appearance.

The discharge is produced from the urethra (and the urethra, and from the lacuna), but is never more than about two or three inches long, in extreme cases. Mr. Hunter says, seldom farther than an inch and a half, or two inches at most. This he takes the quantity of the inflammation. Whenever he begins to examine the urethra affected with gonorrhoea, he always found the lacuna closed with mucus, and more visible than in the natural state. Sometimes it is so enlarged that it is almost completely closed; and the discharge goes from the whole surface of the urethra, and even from Cowper's glands, the prostate and vesicular seminales.

But if the matter were secreted from all these parts, the pus would collect in the bulb, on the scrotum, and thence be emitted in jets; for looking into it in the bulbous part of the urethra without examining it to touch, especially when in a state of irritation and inflammation.

When the inflammation is violent, some of the vessels of the urethra often burst, and a discharge of blood occurs. Sometimes such blood is only put on to give the matter a tinge. In other instances, rectum causes an extravasation by obstructing the urethra.

When the inflammation goes more deeply than the membranous lining, and affects the cellular membrane of the urethra, it produces in it an enlargement of considerable length, the consequence of which is a chancre. (See *Chancre*.)

Mr. Hunter supposed, that the disease is communicated or creeps along from the glans to the urethra, or, at least, from the lips of the urethra to its inner surface, so it is impossible that the infection could not, being rubbed, get as far as the disease extends. He mentions an instance, in which a gentleman who had not been treated with any violent or many means, in all appearance caught a gonorrhoea from a piece of paper, which had adhered to his glans penis in a venereal sore. The infection is accounted for, by supposing that some virus with a clasp had previously been to the place, and had left behind some of the discharge, and that the above gentleman had allowed his penis to remain in contact with the matter till it had dried.

Many symptoms depending on the sympathy of the parts with the urethra sometimes accompany a gonorrhoea. An hæmorrhoea, consisting of venereal and just, and a kind of watery, are felt about every part of the penis. The venereal, venereal, perineum, anus, and legs become disagreeably sensitive, and the urethra often appears to be squagled. An irritable, inflamed,

they in such a way, that the least accident, or even exertion, which would have no effect on this kind at another time, will make them swell. The glands of the groin are often affected sympathetically, and even swell a little, but they do not suppurate, as they generally do when they inflame from the secretion of matter. Mr. Hunter has seen the irritation of a gonorrhoea so extensive as to affect not only the thighs, buttocks, and abdominal system, but have even produced the fever, had a gonorrhoea without being attended with increased venereal pain.

When the disorder, however, of the urethra from sympathy is become violent than has been described, Mr. Hunter termed it a *caput, or species ventralis, gonorrhoea*; but if the patient is very susceptible of such irritation, or of any other kind of which which may excite the venereal, then the symptoms are in proportion heightened. In such circumstances, we sometimes find the irritation and inflammation extend the specific disease, and creep through the whole system. There is often a considerable degree of pain in the perineum; and a frequent, though not constant, erythema is a symptomatic indication of this secretory system and mucous membrane. In these cases, the inflammation is sometimes considerable, and goes deeply into the cellular membrane, but without producing any effect except swelling. In other instances, it goes on to suppuration, thus becoming one of the causes of fistula in perineum. Thus, Gouper's glands may suppurate, and the irritation often spreads from the bladder itself.

When the bladder is affected, it becomes more susceptible of every kind of irritation. It will not bear the least disturbance, and therefore the patient sometimes has water in his urinary tube, and the constant desire of making water takes place; he is obliged frequently to make it, and makes pain in the bladder, and sometimes in the groin, exactly similar to what happens in a fist in the groin. If the bladder be not allowed to discharge its contents immediately, the pain becomes almost insupportable; and even when the urine is evacuated, there remains for some time a considerable pain back in the bladder and groin.

Sometimes, though rarely, when the bladder is much affected, the ureters, and even the kidneys sympathize; and Mr. Hunter has reason to suspect that the irritation might be communicated to the peritoneum by means of the vesiculae.

Mr. Hunter mentions a case, in which, while the inflammatory symptoms of a gonorrhoea were abating, an inflammation of this case on, but in little proportionately well.

A very common symptom attending a gonorrhoea is a swelling of the testicle.—(*See Nerve Hæmorrhoides*.)

Another accidental consequence is a sympathetic swelling of the inguinal glands.—(*See fistula*.)

A third kind is sometimes observed, leading from the glands along the back of the penis, and then directing its course to one of the groins, and affecting the glands. At the part of the groin where the cord takes issue, there is just commonly a swelling. This sometimes happens when an evacuation and a discharge from the penis or glands take place. In one case, Mr. Hunter thought the large vein in the dorsum of the penis was inflamed and thickened.—(*On the symptoms affecting the Secretion and Excretion of the Urine, &c. p. 264.*)

From the above account, the symptoms of gonorrhoea in different cases seem to be subject to infinite variety. The risk here often appears without any pain, and the coming out of the urine is not at all hindered, and after the usual time of the discharge. There is often no pain at all, although the discharge is in considerable quantity, and of a bad appearance. The pain often goes off while the discharge continues, and will return again. In some cases, as I think is not a considerable time, which is sometimes succeeded by pain; though in many cases it continues all the way to the cure. At the same time, the pain is often troublesome and considerable, even when there is little or no discharge. The neighbouring parts sympathize, as the glands of the groin, the testicle, the liver and spleen, the upper part of the thighs, and the abdominal muscles. Sometimes the disease spreads a few hours after the application of the poison, sometimes not till six weeks have elapsed. Lastly, it is often applicable to diseases whether the case is a venereal discharge, or rather was

produced by the application of infectious matter, or only an accidental discharge, arising from some unknown cause.

GONORRHOEA IN WOMEN.

The disorder is not so easily ascertained in women as in men, because they are subject to a *discharge called fluor albus*, which resembles gonorrhoea. A more discharge in women is less a proof of the existence of a gonorrhoea than even a discharge without pain at men. The kind of matter does not enable us to distinguish its condition from a *fluor albus*; for in the latter affection, the discharge often puts on all the appearance of venereal matter. There is no necessary pain, and therefore no reason of disturbance. The appearance of the parts often gives us but little information; for he says Mr. Hunter, I have frequently examined the parts of those who confessed all the symptoms, such as increase of discharge, pain in making water, burning in walking, or when the parts were touched, but I could see no difference between these and *fluor albus*. I know of no other way of judging, in cases where there are no symptoms visible in the person herself, or where the patient has a wish to deny any venereal symptoms, but from the circumstances preceding the discharge; such as having been connected with men supposed to be infected, or her being able to give the disorder to others; which last circumstance, being derived from the testimony of another person, is not always to be trusted in her private remark. But though there may sometimes be great difficulty in forming a judgment of some of these cases, the surgeon may frequently come to a right conclusion, by considering, as Mr. Hunter has suggested me, that, besides the difficulties depending on the constantly severe symptoms of gonorrhoea, that always may be shown by the great debility; the swelling of the stomach; the weakness of the limbs; the pain of the back, always increased by the erect posture; the severe hæmorrhoids; the painful menstruation; together with the very gradual nature of the disease.

From the manner in which the disease is contracted, it is not principally attack the system, a just and allowed with much probability. In many cases, however, it produces a considerable laceration in the inside of the labia, vagina, clitoris, external os, and sometimes the urethra. In certain cases, these parts are so sore, that they will not bear to be touched; the patient can hardly walk, the urine gives pain as it passes through the urethra, and when it comes out it is often with the above-mentioned pain.

The bladder, and even the kidneys, occasionally sympathize. The mucous glands on the inside of the labia often swell, and sometimes suppurate, forming small abscesses, which open near the orifice of the vagina.

According to Mr. Hunter the venereal matter from the vagina sometimes flows down the perineum to the anus, and produces a gonorrhoea or chancre in that situation. The disease in women may probably wear itself out, as in men; but it may exist in the vagina for years, if the testimony of patients can be relied on.

TREATMENT OF GONORRHOEA.

As every kind of the venereal disease is supposed to arise from the same cause, and as we have a specific for some forms, we ought to expect that there would be a certain cure for every one; and therefore, that it might be no difficult task to cure the disease, when in the form of inflammation and suppuration on the urethra. Experience teaches us, however, that the gonorrhoea is the most variable of all symptoms, which leads a cure; and the most uncertain, with respect to its cure. Of the period of the venereal disease, if it ever be a large of this disease at all, many cases continuing a week, many others continuing months under the same treatment.

The only curative object is, to destroy the inflammation and specific mode of action in the parts of the penis, and as they become changed, the poisonous quality of the matter produced will also be destroyed. This affects the cure of the disease, but does not always remove the consequences.

Gonorrhoea is incapable of being continued beyond a certain time in any constitution; and when it is violent, or of long duration, it is owing to the part being very susceptible of such irritation, and readily receiv-

ing it. As no specific remedy for gonorrhoea is known, it is fortunate that one alone will effect a cure. It is worthy of consideration, however, whether medicine can be of any service. Mr. Hunter is inclined to think it not of the least use in more cases than of ten. But even this would admit some consequence, if the cause capable of being benefited could be distinguished.

The nature of cases generally adopted are of two kinds, internal remedies and local applications; but whether pain is primary, we are always to attend more to the nature of the constitution, or to any accompanying disease in the parts themselves, or some combination with them, than to the gonorrhoea itself.

When the symptoms are violent, but of the ordinary inflammatory kind, known by the course of the inflammation not exceeding the specific duration, the local treatment may be either trying or soothing.

According to Mr. Hunter, irritating applications are less disagreeable in these cases, though irritative inflammation is possible, and they may alter the specific course; but as produce this effect their intention must be greater than that of the secreted matter. The parts will afterwards recover of themselves, as soon as the ordinary inflammation.

Mr. Hunter believes, however, that in the beginning the soothing plan is the best. If the inflammation is great, and of the irritable kind, no violence is to be used, for it would only increase the symptoms; and getting should be done that will lead to stop the discharge, as it would put out a stop in the inflammation. The constitution is to be altered, if possible, by remedies adapted to the disposition, and following the disease to its simple form. If the constitution cannot be altered, nothing is to be done, and the action is to be allowed to wear itself out.

When the inflammation has abated, the cure may be completed by internal remedies or local applications which do not operate violently, whereby the irritation might be reproduced. Gentle stimulants may be applied.

But, if the disease has become violent, an irritating injection may be used, in order quickly to get rid of the specific mode of action. The application will increase the symptoms for a time, but when it is left off they will often abate or wholly disappear; and after such slackening stimulatives may be used, the discharge being the only thing to be removed.

When taking pain, and other incoercible difficulties are felt for some time before the discharge appears, Mr. Hunter sufficiently expresses his inclination to recommend the soothing plan, instead of the irritating one, in order to bring on the discharge which is a step towards the resolution of the inflammation; and he holds that to use stimulatives would be bad practice, as by increasing the discharge they would only prolong the cure. When there are strictures or excruciating vesicles, stimulatives should not be used; for while there is a discharge such complaints are relieved.

Mr. Hunter thus expresses himself in regard to the effect of mercury in gonorrhoea: "I doubt very much of mercury having any specific virtue in this species of the disease; for I find that it is too soon cured without mercury as with it, &c. Soluble effluvia, I believe, has the greatest effect in gonorrhoea, that I have known a gonorrhoea take place while the subject was under a course of mercury sufficient for the cure of a chancre. Now have also been known to contract a gonorrhoea when loaded with mercury for the cure of a chancre; the gonorrhoea, nevertheless, has been so difficult of cure as to endanger life."

Mr. Hunter does not say much in favour of evacuations, diuretics, and antispasmodics given internally. He disposes, however, that cathartics, given not specifically on the parts, as the balance compared with any other medicine which may be thought right, may help to lessen the discharge, in proportion as the inflammation abates.

Local applications may be either internal by the urethra, external by the penis, or both. Those which are applied to the urethra seem to produce most efficacy, because they come into immediate contact with the diseased parts. They may be either in a solid or fluid form. A fluid is only a very temporary application. The solid ones, or bougies, may remain a long while; but as gonorrhoea abates infrequently, from their solidity alone; and Mr. Hunter says, the few bougies are used when the parts are in an inflamed state."

though he never saw any bad effects from them, while applied with caution.

At present bougies are rarely used in cases of gonorrhoea, in consequence of the irritation which they produce, and their tendency to bring on a return of the disease.

The fluid applications or injections are less so, and more gentle; and as gonorrhoea frequently gets into such so many of various kinds, we may infer that the same plan would, in time, get well of itself. However, there remains to be done that injections when used have no immediate effect on the symptoms, and hence may have power) though the injection which produces the greatest power is unknown. As injections are not necessary applications, they must be used when, especially when found useful, and not of an irritating kind.

Mr. Hunter divides injections into four kinds, the anodyne, sedative, resolvent, and astringent. According to his doctrine, irritating injections of every kind act in this disease upon the same principle; that is, by producing an irritation at another part, which could be greater than the venereal; by which means the venereal is destroyed and lost, and the disease cured, although the pain and discharge may be kept up by the injection, effects a benefit, which may soon go off when the injection is laid aside. In this way bougies thus produce a cure. Most of the irritating injections have an astringent effect, and give simple treatment when used.

Irritating injections should never be used when they are already much inflammation; especially in constitutions which are liable to be irritated by any such irritation: nor should they be used when an inflammation has spread beyond the specific disease; nor when the vesicles are tender. But when used the discharge coming quickly, these parts have become dry, and when the permanent is very symptomatic of inflammation, and especially if a further should have occurred; nor when there is a tendency to the discharge to irritation, known by the frequency of having water.

In mild cases, and in constitutions which are not irritable, such injections often succeed, and however the disease abates immediately. The phlegm, however, ought to be stopped with cathartics, and not cathartics, till milder methods have failed. Two grains of the jalapineum catharticum, dissolved in eight drops of distilled water, form a very good irritating injection; but an injection of only half this strength may be used, when it is not attended by attended a cure or cure. If, however, the injection, even in this quantity, produces considerable pain in its application, it becomes a prodromic of pain in making water, it should be better avoided.

Sedative injections will always be of service when the inflammation is considerable, and they are very useful in removing the pain. Perhaps the cathartics is again, as well when given by the rectum as when, as when applied to the part affected in the form of an injection. But even opium will not act as a sedative in all constitutions and parts; but, in the majority, short but opposite effects, producing great irritation. Local may be rendered sedative, so far as it would be, flammable, while at the same time it may act as a gentle stimulant. Fourteen grains of opium dissolved in 3vj of distilled water, make a good sedative or anodyne injection.

Diluting body of distilled liquor may, however, be a sedative effect, as it in part removes some of the causes of irritation, by reducing the extent and duration to the bladder when the irritation is there, and so the system is less pained thereby. It does directly may possibly lessen the susceptibility of irritation. The vegetable purgatives of certain seeds are painless, and the cooling ones are astringent. Mr. Hunter does not entertain much opinion, of their efficacy, though some of his patients that have had very experienced less success in making water, when their drink was impregnated with such vegetable substances.

Emollient injections are the most good when the inflammation is very great; and they produce an effect, first, simply by washing away the matter, and then by a soft application to the part, so as to be singularly or visibly by lessening the irritating effects of the disease. Indeed, practice proves this; for a solution of gum arabic, milk and water, or sweet oil, will often lessen the

pass and other symptoms, when the more active ingredients have done nothing, or cannot be so done.

The irritation at the orifice of the urethra is frequently so great that the pain of the syringe cannot be suffered to enter. In this case, an injection should be used till the inflammation has abated; but, in the mean while, fumigations may be employed.

Antiseptic injections act by lessening the discharge. They should only be used towards the latter end of the disease, when it has become mild. But if the disease should begin mildly, they may be used from very beginning; for by gradually lessening the discharge, without increasing the inflammation, we regulate the cure, and prevent a continuance of the discharge called *gleet*. They will have an irritating quality if used strong, and hence increase the discharge, instead of lessening it. Mr. Hunter's experience did not teach him that sea storages was much better than another. The strongest gales, as tragacanth, blood, the balsam, and the vegetable, directed to water, the juice of many vegetables, as oak bark, Peruvian bark, camellia root, and perhaps all the astringent salts, as cream, blue, and white vitriol; the salts of mercury, and also zinc; probably affect much in the same way; though the more changing of all injections is often efficacious. The local use of the little seed properly diluted, has been recommended by Vaguet, Thuillier, and others, as a safe remedy for the stoppage of gonorrhoea. (See *Précis on the Effects of various Articles in the Cure of Gleet*, Vaguet, 1760, vol. 1; and *Nouvelles Méthodes*, Thuillier, 1760, 1761, 1762, 1763, 1764, 1765, 1766, 1767, 1768, 1769, 1770, 2827, 2828, 2829, 2830, 2831, 2832, 2833, 2834, 2835, 2836, 2837, 2838, 2839, 2840, 2841, 2842, 2843, 2844, 2845, 2846, 2847, 2848, 2849, 2850, 2851, 2852, 2853, 2854, 2855, 2856, 2857, 2858, 2859, 2860, 2861, 2862, 2863, 2864, 2865, 2866, 2867, 2868, 2869, 2870, 2871, 2872, 2873, 2874, 2875, 2876, 2877, 2878, 2879, 2880, 2881, 2882, 2883, 2884, 2885, 2886, 2887, 2888, 2889, 2890, 2891, 2892, 2893, 2894, 2895, 2896, 2897, 2898, 2899, 2900, 2901, 2902, 2903, 2904, 2905, 2906, 2907, 2908, 2909, 2910, 2911, 2912, 2913, 2914, 2915, 2916, 2917, 2918, 2919, 2920, 2921, 2922, 2923, 2924, 2925, 2926, 2927, 2928, 2929, 2930, 2931, 2932, 2933, 2934, 2935, 2936, 2937, 2938, 2939, 2940, 2941, 2942, 2943, 2944, 2945, 2946, 2947, 2948, 2949, 2950, 2951, 2952, 2953, 2954, 2955, 2956, 2957, 2958, 2959, 2960, 2961, 2962, 2963, 2964, 2965, 2966, 2967, 2968, 2969, 2970, 2971, 2972, 2973, 2974, 2975, 2976, 2977, 2978, 2979, 2980, 2981, 2982, 2983, 2984, 2985, 2986, 2987, 2988, 2989, 2990, 2991, 2992, 2993, 2994, 2995, 2996, 2997, 2998, 2999, 3000, 3001, 3002, 3003, 3004, 3005, 3006, 3007, 3008, 3009, 3010, 3011, 3012, 3013, 3014, 3015, 3016, 3017, 3018, 3019, 3020, 3021, 3022, 3023, 3024, 3025, 3026, 3027, 3028, 3029, 3030, 3031, 3032, 3033, 3034, 3035, 3036, 3037, 3038, 3039, 3040, 3041, 3042, 3043, 3044, 3045, 3046, 3047, 3048, 3049, 3050, 3051, 3052, 3053, 3054, 3055, 3056, 3057, 3058, 3059, 3060, 3061, 3062, 3063, 3064, 3065, 3066, 3067, 3068, 3069, 3070, 3071, 3072, 3073, 3074, 3075, 3076, 3077, 3078, 3079, 3080, 3081, 3082, 3083, 3084, 3085, 3086, 3087, 3088, 3089, 3090, 3091, 3092, 3093, 3094, 3095, 3096, 3097, 3098, 3099, 3100, 3101, 3102, 3103, 3104, 3105, 3106, 3107, 3108, 3109, 3110, 3111, 3112, 3113, 3114, 3115, 3116, 3117, 3118, 3119, 3120, 3121, 3122, 3123, 3124, 3125, 3126, 3127, 3128, 3129, 3130, 3131, 3132, 3133, 3134, 3135, 3136, 3137, 3138, 3139, 3140, 3141, 3142, 3143, 3144, 3145, 3146, 3147, 3148, 3149, 3150, 3151, 3152, 3153, 3154, 3155, 3156, 3157, 3158, 3159, 3160, 3161, 3162, 3163, 3164, 3165, 3166, 3167, 3168, 3169, 3170, 3171, 3172, 3173, 3174, 3175, 3176, 3177, 3178, 3179, 3180, 3181, 3182, 3183, 3184, 3185, 3186, 3187, 3188, 3189, 3190, 3191, 3192, 3193, 3194, 3195, 3196, 3197, 3198, 3199, 3200, 3201, 3202, 3203, 3204, 3205, 3206, 3207, 3208, 3209, 3210, 3211, 3212, 3213, 3214, 3215, 3216, 3217, 3218, 3219, 3220, 3221, 3222, 3223, 3224, 3225, 3226, 3227, 3228, 3229, 3230, 3231, 3232, 3233, 3234, 3235, 3236, 3237, 3238, 3239, 3240, 3241, 3242, 3243, 3244, 3245, 3246, 3247, 3248, 3249, 3250, 3251, 3252, 3253, 3254, 3255, 3256, 3257, 3258, 3259, 3260, 3261, 3262, 3263, 3264, 3265, 3266, 3267, 3268, 3269, 3270, 3271, 3272, 3273, 3274, 3275, 3276, 3277, 3278, 3279, 3280, 3281, 3282, 3283, 3284, 3285, 3286, 3287, 3288, 3289, 3290, 3291, 3292, 3293, 3294, 3295, 3296, 3297, 3298, 3299, 3300, 3301, 3302, 3303, 3304, 3305, 3306, 3307, 3308, 3309, 3310, 3311, 3312, 3313, 3314, 3315, 3316, 3317, 3318, 3319, 3320, 3321, 3322, 3323, 3324, 3325, 3326, 3327, 3328, 3329, 3330, 3331, 3332, 3333, 3334, 3335, 3336, 3337, 3338, 3339, 3340, 3341, 3342, 3343, 3344, 3345, 3346, 3347, 3348, 3349, 3350, 3351, 3352, 3353, 3354, 3355, 3356, 3357, 3358, 3359, 3360, 3361, 3362, 3363, 3364, 3365, 3366, 3367, 3368, 3369, 3370, 3371, 3372, 3373, 3374, 3375, 3376, 3377, 3378, 3379, 3380, 3381, 3382, 3383, 3384, 3385, 3386, 3387, 3388, 3389, 3390, 3391, 3392, 3393, 3394, 3395, 3396, 3397, 3398, 3399, 3400, 3401, 3402, 3403, 3404, 3405, 3406, 3407, 3408, 3409, 3410, 3411, 3412, 3413, 3414, 3415, 3416, 3417, 3418, 3419, 3420, 3421, 3422, 3423, 3424, 3425, 3426, 3427, 3428, 3429, 3430, 3431, 3432, 3433, 3434, 3435, 3436, 3437, 3438, 3439, 3440, 3441, 3442, 3443, 3444, 3445, 3446, 3447, 3448, 3449, 3450, 3451, 3452, 3453, 3454, 3455, 3456, 3457, 3458, 3459, 3460, 3461, 3462, 3463, 3464, 3465, 3466, 3467, 3468, 3469, 3470, 3471, 3472, 3473, 3474, 3475, 3476, 3477, 3478, 3479, 3480, 3481, 3482, 3483, 3484, 3485, 3486, 3487, 3488, 3489, 3490, 3491, 3492, 3493, 3494, 3495, 3496, 3497, 3498, 3499, 3500, 3501, 3502, 3503, 3504, 3505, 3506, 3507, 3508, 3509, 3510, 3511, 3512, 3513, 3514, 3515, 3516, 3517, 3518, 3519, 3520, 3521, 3522, 3523, 3524, 3525, 3526, 3527, 3528, 3529, 3530, 3531, 3532, 3533, 3534, 3535, 3536, 3537, 3538, 3539, 3540, 3541, 3542, 3543, 3544, 3545, 3546, 3547, 3548, 3549, 3550, 3551, 3552, 3553, 3554, 3555, 3556, 3557, 3558, 3559, 3560, 3561, 3562, 3563, 3564, 3565, 3566, 3567, 3568, 3569, 3570, 3571, 3572, 3573, 3574, 3575, 3576, 3577, 3578, 3579, 3580, 3581, 3582, 3583, 3584, 3585, 3586, 3587, 3588, 3589, 3590, 3591, 3592, 3593, 3594, 3595, 3596, 3597, 3598, 3599, 3600, 3601, 3602, 3603, 3604, 3605, 3606, 3607, 3608, 3609, 3610, 3611, 3612, 3613, 3614, 3615, 3616, 3617, 3618, 3619, 3620, 3621, 3622, 3623, 3624, 3625, 3626, 3627, 3628, 3629, 3630, 3631, 3632, 3633, 3634, 3635, 3636, 3637, 3638, 3639, 3640, 3641, 3642, 3643, 3644, 3645, 3646, 3647, 3648, 3649, 3650, 3651, 3652, 3653, 3654, 3655, 3656, 3657, 3658, 3659, 3660, 3661, 3662, 3663, 3664, 3665, 3666, 3667, 3668, 3669, 3670, 3671, 3672, 3673, 3674, 3675, 3676, 3677, 3678, 3679, 3680, 3681, 3682, 3683, 3684, 3685, 3686, 3687, 3688, 3689, 3690, 3691, 3692, 3693, 3694, 3695, 3696, 3697, 3698, 3699, 3700, 3701, 3702, 3703, 3704, 3705, 3706, 3707, 3708, 3709, 3710, 3711, 3712, 3713, 3714, 3715, 3716, 3717, 3718, 3719, 3720, 3721, 3722, 3723, 3724, 3725, 3726, 3727, 3728, 3729, 3730, 3731, 3

epithelial plantar on the palm, or the burn, where the surface of the bladder originates; or, a small blister on the perineum. In another place he mentions lock, stricture, urethra, and gonorrhoea, among the proper causes.

See Med. Testimon. See Herma's Materials.

For a more full account of gonorrhoea, according to the above authorities, see *A Treatise on the Venereal Disease*, by John Hunter, from page 59 to 66.

ON THE QUESTION WHETHER GONORRHOEA IS EXALAN A FORM OF THE VENEREAL DISEASE.

The foregoing remarks, and others in Mr. Hunter's work, would lead one to believe, that the poison of gonorrhoea and the venereal virus are the same. Here it is my duty especially to state the arguments which have been urged for and against this important question.

Mr. Hunter assumes, first, that he has seen all the symptoms of less venereal origin than gonorrhoea; and, that he had even produced venereal diseases by inoculating with the matter of gonorrhoea; and that he afterwards repeated these experiments in a manner in which he could not be deceived.—(P. 20, *et seq.*)

Mr. Hunter's experiments, it is true, have been repeated with a different result; but, as a late writer has remarked, may we wonder at this, when we consider from how many causes gonorrhoea may arise, and how impossible it is to distinguish the venereal from any other?—(On the Venereal Disease, by A. Adams, M.D. p. 56, ed. 2.)

Another argument advanced by Hunter, in favour of the poison of gonorrhoea and chancre being the same, is the probability that the Ottomans had the venereal disease propagated to them by European sailors, who were afflicted with gonorrhoea; for these men usually supposed to have had a chancre during a voyage of five months, without the penis being destroyed.

It is impossible, however, to say what time may elapse before the application of the venereal poison to the parts and the commencement of the ulceration. Therefore, Roushew's sailors, attacked by Mr. Hunter, might have contracted the infection in Rio de la Plata, but actual ulcers on the penis might not have formed till about five months afterward, when the ship arrived at Oran.

In answering to explain why a gonorrhoea and a chancre do not equally produce less venereal, and why the medicine which almost universally cures chancre has no effect on gonorrhoea, a modern advocate for Mr. Hunter's doctrine says, that we must take into consideration, that the sort of the two diseases is different; that the same cause may produce different effects upon different parts, that the same poison, when mixed with different fluids, may be more or less violent in its operation; and that there may be greater or less attraction of certain fluids to a part, according to its sensibility and disposition.—(Lectures on the Venereal Disease, by A. Adams, M.D. p. 4.) Mr. Adams says truly, however, p. 6, that if the physician could neither hit clearly and distinctly marked chancre, nor accommodate the system to any one medicine, the question is complicated. It would be no instance, produces these effects, unless it had the power of doing so. This writer arrives toward some cases to prove, that the poison of gonorrhoea may produce gonorrhoea or chancre; but the point of this work only affords room to observe that these instances are by no means decisions of the point, because some objections may be urged against them, as indeed Mr. Harvey himself allows. That Mr. Hunter's cases are inconsiderable, I have previously endeavored to explain in the last edition of the *First Lectures on the Venereal Disease*.

Why does not gonorrhoea occasionally produce ulceration on the penis? Mr. Harvey tries to solve this question by saying, that the product of the venereal inflammation, the dissolved contents of the small vessels of the urethra, are thrown out of these open-mouthed vessels into the canal, without any breach of these vessels, which otherwise would be a necessary consequence.

Why does not gonorrhoea equally communicate the venereal infection? In gonorrhoea, says he, however, the discharge is very plentiful; it is not, in general, attended with ulceration; the poison is much more watery, and mixed with a mucus and particles that, if it is deposited in the urethra and its branches, where

little or no pressure is applied, and it flows easily out of the canal. In chancre, there is a breach of the vessels, the poison is not easily chased, &c.

Why does not chancre generally in the same young produce gonorrhoea and venereal infection? Mr. Harvey, in answer, expresses his belief, that these diseases are not very frequent. He says, in his known persons having a chancre, which continued for months, became affected after that time with a chancre without any further exposure. He supposes it, that the matter of the chancre had introduced itself into the vessels and produced the chancre; though he reasons, many would explain the circumstance by assuming that these diseases and gonorrhoea were both venereal, and that the same time by two different poisons.

Mr. Harvey assumes, that the products of the venereal inflammation the adjacent parts less susceptible of the influence of the other.

Mr. Harvey concludes his second chapter with insisting on the idea, that the matter of gonorrhoea is essentially pus, but of a more purulent nature than that of a chancre. However, when he considers chemical differences, as deriving the poison from these is the matter, and from pus to the dry parts, it is not to explain the last of the above questions, every one must find more than a work which contains some sensible observations should comprehend this most remarkable case.

Mr. Whistly also supported the opinion, that the matter of gonorrhoea and that of chancre are the same.—(On Gonorrhoea Venerea.)

Another defender of this side of the question is Dr. Brederick, who endeavours to prove the identity of the following positions: 1. That the poison which produces the chancre does also, like the chancre, produce any venereal symptoms on the testis, or less likely. 2. That the poison of the chancre produces chancre, and that the poison of chancre produces a chancre. 3. That ordinary cases of chancre, if not accelerated, the cure of a chancre; but that, in its ordinary, every chancre may be cured and without mercury, and without any danger of forming a chancre.

His arguments run thus:—The poison which causes the chancre, occasionally produces the chancre, and that most of them exists only a superficial inflammation in the membrane of the testis, without any chancre. Hence, chancre cannot easily take place, the poison being out of the centre of the inflammation. And he has seen chancre with no other in the testis, followed by the most dangerous symptoms of chancre. He mentions the urethra being affected with a large quantity of matter, so the thing depending the common disposition of matter, which is occasionally more when the matter is not secreted outward, or is voided with the urine, that in many cases, where he had reason to believe both parties, he was convinced that the chancre was communicated by a person affected with a simple gonorrhoea, and vice versa, that a chancre had been the consequence of an infection from a person having merely chancre. He says that if a patient with a venereal running chancre did not take care to keep the prothod and glass perfectly clean, chancre will very often be produced. He seems a great enemy to the cure without mercury; yet, repeated experience has shown him a more certain, he always has accomplished. Mild cases, without chancre or ulceration in the urethra, may certainly be cured with mercury, and a great deal of mercury; and though mercury should be given, it would not have the least effect, not because the disease does not proceed from the venereal poison, but because it is out of the course of the circulation. He concludes, that the general use of mercury in injections will surely cure in these cases. But when a chancre is joined with ulceration in the urethra, it is always cured more easily and expeditiously with mercury, and is properly curable without it. A few also history cases attended with ulcers in the urethra. He allows, that all cases are not venereal without mercury. (On Venereal Diseases, by A. Adams, M.D.)

One argument urged against the identity of gonorrhoea and chancre is, that gonorrhoea was described as a symptom all nearly half a century after the whole symptoms of the venereal disease were known. Physicians are aware the fact that gonorrhoea is a symptom of the venereal disease. "If, however," says Dr. Adams, "venereal gonorrhoea was quoted

all about fifty years after the first forms of the disease were described, when does this prove, but that gonorrhoea was so common as to be disregarded as a symptom of the new complaint? Can there be a doubt, from the caution given by Meigs, that gonorrhoea was considered as contagious in his days? During the classical age, we find inaccuracies in the arbitrary passages were applied to inflammation; and the policy of several states, before the siege of Naples, made laws for preventing the health of such as would pass themselves with public works instead of discharging the duties of soldiers.

This is enough to lessen our surprise that gonorrhoea should be considered for long time after the appearance of the venereal disease. But we far less from proving that the two infections are different, that the former infection may not draw its origin from their identity. For if by this time the venereal disease began to be so far understood, that secondary symptoms were found the consequence of primary ones in the genitalia, it is most probable, that the first suspicion of venereal gonorrhoea arose from the occurrence of such secondary appearances, whose far other primary symptoms could be traced.—Adams, on Medical Jurisprudence, p. 56, et. 23.

In visiting the arguments maintained by the best modern writers to repel the attacks made on the doctrine that gonorrhoea and chancre arise from the same source, we have been compelled to discuss the solid grounds on which the opponents venture to maintain a contrary theory.

The arguments of Mr. H. Bell are quite at variance with those of Huxham, Sawrey, Swedmark, Adams, Havers, &c.; but my limits will only allow me just to enumerate a few of his leading arguments.

If the matter of gonorrhoea and that of chancre were of the same nature, he contends which that person with a chancre only can communicate to another, not only every symptom of gonorrhoea, but of gonorrhoea; and that matter, with gonorrhoea only, can give to all with whom he may have connection, chancre, with their various consequences. This might indeed be a very frequent occurrence; whereas all allow that it is even in appearance very rare.

On the supposition, that the matter of gonorrhoea and chancre being the same, the latter ought to be a much more frequent occurrence than the former, from the greater ease with which the matter of infection may, in every instance, be applied to those parts as well as to the produce chancre, than that of the chancre, where, instead of chancre of infection, it almost always creates gonorrhoea. It is difficult to conceive how the matter, by which the disease is communicated, should be so common to the venereal; while at the same time the parts, particularly the penis, least exposed to it, and yet gonorrhoea is a much more frequent disease than gonorrhoea. Cases of gonorrhoea are in proportion to those of chancre, according to Mr. H. Bell's experience, at times in ten to one. It is evident that the very reverse should happen, if the two diseases were produced by the same kind of matter.

I need not adduce other arguments, as the reader must be already acquainted with any worth knowing, from what is said in the previous part of this article.

The great practical recommendation depending on the possibility of the venereal disease arising from gonorrhoea, whether necessary should not be neglected, in all cases, with the view of preventing such a consequence.

Writing, on my own part, all attempts to decide the point, whether the matter of a chancre and that of one of gonorrhoea are of the same nature, I shall merely content myself with stating, that, so far as my observation and inquiries extend, the majority of the two practitioners of the present day consider the exhibition of mercury unnecessary and consequently improper, in all cases of gonorrhoea. This fact almost amounts to a proof that, if venereal symptoms do ever follow a chancre, they are so rare, and I may add, always an irreparable badler comes, that the employment of mercury, as a preventive, would ruin the whole, do more injury than benefit to mankind; and this even admitting (what to my mind has never been universally proved) that the matter of gonorrhoea is really passing, in a very few instances, of giving rise to the venereal disease.

The reader must weigh the different arguments himself. Some of Mr. H. Bell's reasoning is certainly untenable, as Mr. Henry has clearly shown; but the latter also is not infallible in many points, which he strives to defend.

GORGENT, An instrument used in the operation of lithotomy, for the purpose of cutting the prostate gland and neck of the bladder, so as to enable the operator to introduce the forceps and extract the stone. It is, in fact, a sort of knife, at the end of which two hook-like pins the groove of the staff and blades of being pushed into it into the bladder.

Besides cutting pipes, continued by the growth, the design, there are also many more, intended to be introduced into the urethra, when their capacity serves as a guide for the forceps into the bladder.

GRANULATIONS. The little, gran-like, fleshy bodies, which form on the surfaces of ulcers and surrounding wounds, and serve both for filling up the cavity and bringing together together and healing their sides.

We need not describe the operations of nature, in bringing parts so nearly as possible to their natural state, where disposition, action, and structure have been altered by accident or disease. Having found parts irreparably broken to form new matter upon surfaces in which there has been a breach of continuity. This process is called granulation, or incorporation, and the substance formed is called granulation tissue.

Granulations are an secretion of animal matter upon the wounded or exposed surface. They are formed by infestation of the compound epithelium of the wound; and when new substance has not been very fully supplied, and in which new cells are formed. Hence, granulations are extremely vascular; indeed, more so than almost any other natural substance. "That this is the case," says Mr. Hunter, "is open to every eye." I have often been able to trace the growth and vascularization of granulation substance. I have seen spots a few weeks before, perfectly smooth, in every visible respect, to granulation tissue. I have not attempted to pull it off, and the next day of drawing I have found it was very substance was very soft, by rubbing or touching it with a probe, it has been freely. I have observed the same appearance on the external of a bone that has been laid bare. I have removed off some of the external surface of a bone of the hand, to see if the surface would granulate. I removed the following day, that the surface of the bone was covered with a white substance, having a form of bone. When I passed my probe into it, I did not find the bone bare, but only its substance. I introduced the

substance to be impossible lymph thrown out from inflammation, and that it would be forced off when absorption ceases; but on the succeeding day I found it vascular, and appearing like healthy granulations." The vessels in granulations pass from the original parts to their bases, and thence towards their external surface, in loosely regular, parallel lines. The surface of the new substance has the same disposition to contract just as the parts which produced it. The surface of granulations are very convex, are covered of themselves, having a great many small points of elevation, so as to appear rough. The smaller earthy particles, the most healthy earthy granulations. The colour of healthy granulations is a deep fawn red. When dried, they are whitish, and have only a light brown surface. Healthy granulations, when exposed to air, rapidly lose their colour with the surface of the surrounding skin, and when a little higher, but when they dried, they are white as a growing disposition, they are healthy, become soft, suppurate, and without any disposition to form skin. Healthy granulations are always found to be in such cases, so as to be the result of healing parts.

Granulations are not easily healed, as the skin of an abscess around the surface of the hole.

They are not rendered with the same powers as parts naturally formed. Hence they have healthy absorption denied. Hence they have healthy granulations denied when more are needed, and even when they have been formed, have been explained in the article Consumption.—See *A Treatise on the Blood*, Inflammation, &c. by John Hunter, p. 417, 418, 1794.

It is a question whether granulations can ever be formed without suppuration. Mr. Hunter seems inclined to think that they may occasionally be produced without it, and he supports his opinion by the relation of the formation of a granulated testis, in which he observed a granular substance granulations. Dr. John Thomson, in the third book, declares that he has never seen any thing which he considered as an example of a granulation, and with loss of a granulating surface, where granulation formed.—See *Lectures on Inflammation*, p. 488.

The small process by which the blood vessels, nerves, and ducts of granulations are formed, is still among the vessels of nature. The observations of Mr. Hunter on the subject quoted only to confirm. "The growth of nerves and their development is a first formed from granulations (says Dr. J. Thomson), is a subject of great difficulty with the growth of blood vessels in the same structure. Their development in granulations is preceded by the parts which it is not so quick, making, or wiping, the surface of a new. Even the granulations, which arise from the surface of bone are sensible (a specimen not submitted by Mr. Andrew Cooper, though he is not very well able to prove the sensibility of the larger branches of nerves, from which the newly formed and sensible nerves and elements in the granulations are immediately derived. All the difficulties which I formerly mentioned to you, as occurring in the explanation of the nature in which vegetable lymph or granulations are produced with blood vessels, present themselves to me now. We begin to reflect on the matter in which the same granulations are produced with nerves, and these difficulties are still increased, when we suppose that the same granulations are in the state of a few fibres provided, not only with blood vessels and nerves, but also with a system of absorption. The existence of ducts in granulations is proved not only by the changes of such matter as are these daily changes, becoming granular, in the healthy state, and then, when and more compact, but also, by the frequent changes in white or in part of a granulating substance in the process of absorptive absorption."—See Thomson's *Lectures on Inflammation*, p. 419. According to Mr. Andrew Cooper, granulations which spring from parts united with great sensibility, the granulations are extremely sensitive; but granulations which arise from bones, he says, have no sensibility whatever. These observations are qualified with the condition, that the bone be uninfected, and it is acknowledged, that granulations arising from the calcified structure of bones are sometimes extremely sensitive. He describes granulations from bones as quite insensible, and those from synovial membranes as possessing very little sensibility.—See *Lectures on*

1, p. 222. Every young doctor of some of us knows who has been too active of the red prescription system, and has learned from experience, that granulations are diminished with absorbent, venous, and the mercury just be absorbed from the surface of skin, and being in an exhausted-for solution of the parts. It is observed by Mr. Andrew Cooper, that in many cases of ulcers, the granulations are not good absorbent surfaces; but that when the skin has been united a red white, they readily take into the system new granulations which may be applied to them. Thus, when old ulcers are injected with a solution of the acetate of mercury, with the view of stimulating them to heal, the patients are sometimes surprised to see the mercury being absorbed by the system. Mr. Andrew Cooper has seen the same effect produced by the application of the lotion of lime-water and the acetate of mercury in nearly in the nature of ulcers. Indeed, the absorbent power of granulations is frequently the means of producing beneficial effects upon the constitution, by the introduction of dissolved substances into the circulation. Thus, when applied to sores, it often succeeds in the system, and, on this account, it is regarded as a powerful external remedy. Mr. Andrew Cooper gives one instance, in which the patient seems to have been poisoned by the indolent appearance of ulcers, to a fungus of the eye. Ulcers, also, when applied to the surface of sores, in very readily absorbed, producing similar effects to those which arise from granulations upon the stomach. Thus, when the quantity absorbed in two great, extensive ulcers, which were in the head, and beyond of the system, an absorption, which restores the system, and absorption of ulcers granules to their normal.—See *Lectures*, vol. 1, p. 419, 420. A temporary granulation has been known to be produced by the absorption of the tannin of benzoic acid from the surface of a soluble and granular.—See *Thomson's Lectures on Inflammation*, vol. 1, p. 419.

GUALACUM. Many writers of the last century thought this was a very specific in the venereal disease; and the celebrated Boerhaave, in the eighth book, maintained the same opinion. Mr. Pearson mentions that when he was first introduced with the cure of the Lock Hospital in 1751, Mr. Thomas and Mr. Williams were in the habit of giving great confidence in the efficacy of a decoction of gualacum root. This was administered at such doses as had already employed the usual quantity of mercury, but when complained of venereal parts, or of gonorrhoea, syphilis, or other, and such other effects as the venereal virus, connected with secondary symptoms as had not yet had a course of mercurial diseases. The first consisted of rashes and hard swellings; then red blotchy spots of the face were taken every day, the next high was used twice a week; and a course of antimonial wine and barkwater, or Dover's powder, was constantly taken every evening. Decanting infusions of bad was not deemed necessary; but when it was required to the region of having syphilis, with a view of exciting perspiration, often practiced; and only a small dose of the skin was used. This treatment was attended with singular advantage to those, whose syphilis had not failed injury from the disease, ingested, and mercury. The strength increased; but when blood examinations were completed; and then venereal symptoms, which would have been associated to mercury, were yielded to patients.

Besides such cases, in which the good effects of gualacum seemed to be considerably increased in a woman for the first time, the medicine was also found given by some, on the first attack of the venereal disease. The disorder being three months, a woman was considered to be an excellent case, when frequent rashes followed, yet, as these partly refer to the skin (though, in repetition was not left to Mary Thomas also, which got well, with probably the really venereal cases. Mr. Pearson remarks, that, in syphilitic affections, it may, indeed, prove like a true antidote, suspending for a time the progress of certain venereal symptoms, and relieving, as it possesses absorbent; but, in common, the experience has shown that the unabsorbed were performed more to the constitution.

Mr. Pearson would guarantee of little use in case of the bones, except when it proved syphilitic; but that was then sufficient to announce an accident. When the constitution has been injured by mercury failing,

contaminant, a thickened state of the ligaments, or perforations, or fistulous, and suppuration. Mr. Pottson says, these effects will often decide during the restoration of the denervation. He says it will often happen, for a short time, the progress of certain secondary symptoms of the large venous, the gastric, action of the inside, mental irritations, and even hopes. Mr. Pottson, however, never knew any instance, in which patients employed the remedy, and he contends, that the being occupied with necessary business increases the virtue of this remedy, because its bad effects, are diminished. The necessity of giving a sufficient quantity of it. He has seen good effects produced by its use in various diseases, the strict, and sometimes effectiveness of the denervation of ligaments.—(See *Pottson's the History of Pottson's Art in the Cure of Lungs Pottson*, vol. 2, 1807.) Many of the foregoing observations on the causes of gangrene is applicable to the secondary effects of the fact, now so completely established, that the disease is generally capable, in the end, of a spontaneous and lasting cure.—(See *Pottson's* *Journal*.)

GUMMA. A soft tumour, so named from the resemblance of its contents to gum.

GUN-SHOT WOUNDS receive their name from the manner in which they are produced, being generally caused by hard, solid, metallic bodies, projected from cannons, muskets, or some other species of firearm. With such injuries, it is also usual to comprehend a variety of accidental wounds arising from the explosion of shells, or the various small pieces of shrapnel from muskets, or missiles of wood or iron, or large, are driven about. Gun-shot wounds are the most common species of the traumatic kind; and when it is to be said of these, will imply, rage, or loss, in all contused wounds, according to the degree of violence. They are particularly distinguished by what the French surgeons are fond of calling a *shock*, a consequence of this cause. The extensive contusions and fractures accompany gun-shot wounds, depend upon the velocity with which the bodies possessing them are propelled. The parts touched by the ball are immediately converted into a blackish mass, the colour of which must be as extensive as possible, and being produced by gunpowder being kindled, and a small portion of lead with which they come into contact. But reason and experience have now proved, that whatever may be the velocity of a projectile, it never acquires in its passage any perceptible heat. Indeed, a modern writer asserts, that such a degree of heat as would be requisite to make a ball burn parts in its passage, would totally melt it.—(Rush, *Medical Jurisprudence*, vol. 1, p. 217, vol. 2.) In general, gun-shot wounds do not bleed much, unless large blood-vessels be lacerated; the external surface is often livid; and the shock, the stupor, the insensibility, or the labour done to the nerves, may be more or less, as the part is hit, or the force of the blow, or the nature of the body, or the state of the system.

However, as Dr. Hennen most truly observes, "the effects of a gun-shot wound differ so materially in different tissues, the appearances are so various, according to the nature of the part wounded, and the greater or less force with which it has been struck, that no affirmative rules of diagnosis can be laid down as its necessary concomitants. If a musket or pistol ball has struck a fleshy part, without tearing any external blood vessel, we are to have above the size of a marble, that the ball itself will, a night or less, be surrounded by, turned livid; and if it has passed through the parts, we find an external edge, and a more recent and larger defect at the point of its exit. The hemorrhage is in this case very slight, and the pain is moderate, inasmuch that, in severe instances, the wounded part is not worse of the living, nor of any injury. If, however, the ball has lacerated a vessel, or nerve, the hemorrhage will probably be profuse, or the pain of the wound severe, and the power of the part lost. After this we will have a thick crust of coagulated blood, or a crust of pus, which, without exciting the slightest symptoms of heat, or suppurative action; and when they are, they will rarely argue, as the common motto of the theory; while a truly profuse, intense venous, profuse preparation, and universal oedema will arise either on the receipt of a slight shot wound. This tissue, which has been so much talked of, and which is an inexperienced eye is really surprising, is now followed by a menstrual of some of

spots, or by an effusion; but above all by the tenderness and sympathetic nature of the surface, and his observation of the patient's safety.—(Pottson's *Art*, vol. 2, p. 22, vol. 3.)

On the other hand, it is correctly noticed by Mr. Gutter, that the laceration of the constitutional state of a part ought to excite great suspicion of serious injury; and when wounds have been received in such situations, or bear such appearances, or tend to it, it is doubtful whether any part of vital importance has been injured or not, the manner in which the external local perturbation, may be assisted to evidence of the fact, when other symptoms more indicative of the injury are wanting; and under all such circumstances, every extreme measure should be delayed.—(Gutter's *Art*, vol. 2, p. 11, vol. 3.)

Regarding the general character of gun-shot wounds, and to what much as large wounds be injured, it is a fact which necessarily depends upon the degree of violence usually attending these injuries. But it is also true, as the preceding author has stated, that all though some gun-shot wounds bleed but little at first, there is in the greater number of cases more or less of blood, and to wounds of vascular parts, like the face and neck, the quantity lost is often considerable, though the most external laceration may not be deep.—(Gutter's *Art*, vol. 2, p. 11, vol. 3.)

In gun-shot wounds, another circumstance of importance, which is often mentioned in other cases, viz. when a large artery is partially divided, the bleeding is more profuse and dangerous than when the vessel is completely severed, and the hemorrhage, if not stopped by a ligature, or other means, will often interfere with the patient's life. Thus, Mr. Gutter speaks of a case in which life was lost from wounds of the femoral, brachial, and axillary arteries, so divided as to stop the bleeding, the hemorrhage having been stopped.—(p. 11.)

Dr. Andrew Bane introduced some remarks upon the subject of gun-shot wounds, upon the most false, and more highly prejudiced, premises both in their history and treatment, and particularly respecting what have been falsely named *Wound Contractions*. Contractions and being sometimes produce dreadful degrees of injury, without excitation any breach of continuity in the integuments. This observation is so contrary to fact, that the authors and those who usually have read and broken to others, without the least bit of a wound at all. Such cases were for a long while ascribed to the violent muscles supposed to be contracted to the air by the ball itself. It was imagined, that the elastic fluid, being rapidly displaced by the shock of the projectile, was capable of making such pressure as extruding matter, as to destroy their texture. But how could this violent pressure originate in the midst of the open and unobscured air? If this theory were true, the effect in question would constantly happen, whenever a ball passed near any part of the body. The contrary, however, is so much the case, that pieces of soldiers' and sailors' hats, of their buttons, clothes, and even hair are shot away in every battle, without any other noticeable being done.

In consequence of the manner in which such injuries of the soft parts, and even of the bones, attended with any breach in the skin, have been supposed to be produced, they have been erroneously termed *wound contractions*. In fact, these cases are very uncommonly acknowledged by all the most accurate observers to be produced from the cause to which formerly they were always ascribed.

The air does not move with the same velocity as the ball, but its motion is less, in proportion as it is a more elastic matter, and more too little is exerted for such a violent degree of injury. The air in which the ball enters, only communicates its greatest motion in a direct line before it; and will never irritate the part undisturbed by the ball itself. It is only the air displaced laterally by the ball that is supposed to do injury, and it is rather to be greatly admired. The violent consequences of sudden explosions, and the effects produced on the organs of hearing, by strong contractions of the air, prove nothing relative to the point in question. Lastly, experience does not confirm the reality of such *wound contractions*; for cannon-balls often pass all whole members, without the slightest mark being on the most exposed.—(See *Le Voyer*, in *Mémoires de l'Académie de Médecine*, vol. 2, p. 26.)

An eminent professor, who visited the continent for the purpose of seeing the wounded after the battle of Waterloo, fully coincides with M. de Vacher and all the moderns upon this subject. "We saw, and were instructed of many instances in which cannon-balls had passed through the parts of the body, and had removed portions of the vessels and osseous structures, without producing the slightest injury of any kind. In other instances, portions of the body itself were removed by cannon-balls, without the contiguous parts having been truly injured. In one case, the head of the man was carried off by a cannon-ball without respiration being at all affected; and in another very remarkable case, the external part of the ear was shot away, without even the power of hearing being sensibly impaired."—(See Report of Observations made in the British Military Hospital at Brüggen, &c. by J. Trauer, p. 22, Edin. 1816.)

I could cite many more, which I have seen myself, in proof of the truth of Le Vacher's opinion; but the proof is now so universally admitted, that I shall merely add one observation that occurred to the notice of many as well as myself. At the battle of Marston, in 1213, a cannon-shot shattered the legs of two officers, so badly, that the limbs were amputated. These gentlemen were walking at the moment of the accident in the village of Marston, taking hold of the arm of my friend Alexander Simpson, M.D., of the 20th regiment, who was in the middle. Now the ball which produced the injury did not do the slightest harm to the latter gentleman, although it must have passed as close as possible to his lower extremities, and must probably have struck them.

Neither can what have been superficially called wound-contusions be attributed to an electrical shock on the parts, in consequence of the ball being rendered electrical by friction in the caliber of the gun, and being off the mouthpiece as it passes by (vide Francis Richardson, 1. *ibid.*, p. 56); for metals never acquire this property from friction.

The smallest impetus to the air is communicated by the ball itself. Its producing a violent concussion, without tearing the skin and entering the limb, as it is ascribed to the oblique distance in which it strikes the part, or, in other instances, to the resistance with which the ball strikes the surface of the body, in consequence of its having lost the greater part of its momentum, and acted principally by its weight, being, in short, what is called a dead ball. Daily observation evinces that balls, which strike a surface obliquely, do not penetrate, but are reflected; though they may be impelled with the greatest force, and the body struck may be at rest and yielding as water. Thus, therefore, is the course of the ball, not only exposed on the surface of the human body, but also in the substance of a limb which it has entered. Thus, a bone, a tendon, &c. may change the direction of a ball which has taken them at an obliquity. Hence, it is manifest, how it happens that the track of a gun-shot wound is not always straight, and how balls sometimes run along the circumference nearly all round the body or limb.

The causes of several of the peculiarities attending gun-shot wounds are to be sought among the laws by which moving bodies are prevented, not by which the mechanical effect of a ball propelled against any part of the body, must therefore be determined. The form, the momentum, and the direction of the shot that is received; the position, and the variety of structures, or, in other words, the variety of density and powers of resistance, in the part receiving it, must always be considered, in order to account satisfactorily for the effects which it produces. And, though, says Mr. Chevalier, in many cases, a mathematical replication of the course of the ball cannot be given, this same victory gives the want of data, the laws of matter being fixed and invariable. But when the data are known, as, for instance, the velocity and direction of the shot, the position of the patient, or of the wounded part at the time of the accident, and the structure of the parts penetrated, a track may probably be formed, and the course of the ball may generally be formed, then if those circumstances had not been repeated.

On the principle of the density and resistance of parts, attempts have been made to explain the ready absorption of shock, which is given, in many instances, to the whole system by gun-shot wounds,

and which is so represented, by writers on this subject, to be given attended with pain and even alarming effects, extending not only over the injured part, but all during the system at large. Thus, a shot striking against a tendon of a bone, in one of the extremities, will produce a greater commotion than if it struck only against softer parts. A shot striking a muscle is more violent than a commotion than if it struck against the same part of the same muscle at rest; and a shot striking the head of a vessel, the liver, &c., by its violent impact, will generally bring on dangerous commotion of the whole system, with which its direction of these parts are so closely connected.—(V. *Observations on Gun-shot Wounds*, part 1, vol. 1.)

Regarding the mechanical effects of the commotion, I am disposed to think, with Mr. Chevalier, that they have been rather exaggerated, and that in reality a more accurate explanation of the manner of the system might be derived from other considerations.—"A shot during the passage (says he) will cause an instantaneous commotion of the whole system, but the motion effected by the part has little to do with it; it is the loss of the organic functions, indirectly connected with life, that is the cause of the commotion. In this sense, however, I do not conceive, that the general effect of the system depends upon the shock received, but on the effect the injury communicates to the soft parts of the system."—(On Gun-shot Wounds, p. 26, &c.)

A ball, when it strikes a part of the body, may cause four kinds of injury. 1. It may only render a commotion, without penetrating the part, as, in some of its being too much angled, or of the oblique way in which it strikes the surface of the body. 2. It may enter and lodge in the substance of an organ, in which case the wound is usually an aperture. 3. It may penetrate and through; and then there are two openings, one at the entrance, the other at the exit of the ball. The commotion of the aperture, where the ball entered, is usually depressed; that of the opening, from which it came out, elevated. At the entrance, there is commonly more commotion, than at the exit of the ball. The former opening is generally narrower; its rim wider and more irregular, especially when the round smooth figure of the ball has been changed by its having struck a bone. 4. A cannon ball may tear off a whole limb.—(Richard, *Encyclopædia*, art. *Wounds*, &c.)

Gun-shot wounds offer very few kinds, according to the kind of body projected, its velocity, and the nature of the peculiarities of the parts injured. The projected balls are mostly leaden, sometimes tin-plated, sometimes pieces of broken shells, and very often, as I have already said, splinters of wood. The velocity of the motion which the projectile, from the violent passage of the ball through them, there is most commonly a part of the wound surrounding the wound downward, which afterwards thrown off in the form of a spray, generally covering such wounds with lead by the first intention, and looking most of them extremely repulsive. This does not take place equally in every gun-shot wound, nor in every part of the same wound; and the difference commonly arises from the variety in the velocity of the body projected, and where the ball has passed with little velocity, which is sometimes the case at its entrance, but still more frequently at its exit, the wound, the injury may often be limited to the first intention.—(J. Hunter, p. 372.)

And I had the pleasure of reading, in a recent edition of a valuable book on gun-shot wounds, I do not know that, at the present day, any surgeon entertained the idea, that the whole track of a shot, whether it was from a musket, or a cannon, and though it was in a Gun-shot Wound, p. 23, &c. 24; but if (as Chevalier prevails, it is plain from the preceding statements, and the authority of Mr. Hunter cannot be shaken by it) is supposed. At the same time, I believe, that very few surgeons will be inclined to question the statement of Mr. Hunter's account of the spread of a wound, or a degree of commotion, or of the commotion of a part of the nature of a wound, particularly in the vicinity of the entrance of the ball or the exit, or the commotion about the current momentum of the separation of such enough before the parts will be torn, and whether the dead parts be driven off in small fragments with the missile, or larger portions, the fact is still correct.

Foreign bodies were frequently taken in gun-shot wounds from the effects, and the commotion of the

knife. Pieces of clothing or other things with the ball driven into them are found. 2. The ball is soft. 3. Large quantity of blood. It is only when the ball strikes the solid bone, remains in situ, and goes still through the part, that the wound can be then truly fatal. Fracture of bone is the cause of numerous remarkable symptoms, by irritating sensitive parts, and exciting just inflammations, osteitis, osteomyelitis, long suppurations, &c., and the more violent, putrid, and fatal they are, the more likely they are to induce them in us. Hence sprains of bone are generally the cause of it. (See *Fracture*.)

The great company and weight of the bodies produced in the immediate times by gunshot wounds, and such as are so remarkable in any serious case of fracture. When I was with the army in Belgium in the year 1815, I had in my hospital at Brussels several fatal gun-shot fractures of the thigh, caused by rifle-shot wounds. The fracture in some of these cases gave rise to extend two thirds of the length of the bone. This fact is noticed by Mr. Gosselin. "The fracture of the hip artery and below the immediate part struck by the ball, and, so far as the artery is concerned, the fracture downwards than upwards, as that, from a fracture in the middle of the thigh, I have often seen the bone united into the coxal, and even upwards of the entrance of the femoral." &c. (*On Gun-shot Wounds*, p. 138.)

When the ball strikes a bone, the contusion produced is smaller, sometimes, in kind, sometimes, so be added by those directly sustained. When slight, its effects are confined to the injured part; but sometimes they extend to the neighbouring joints, in which they produce inflammation and swelling.

If the sanguiferous vessel is purged of blood, that when a contusion takes off a part, it produces a violent contusion of the whole body, and a general suppuration of all its functions. This, however, is by no means always true. I saw, some years ago in London, a young soldier, whose arm and leg were completely torn off at the shoulder, by a cannon-ball from one of the guns of the Malabar, in Africa, 1805; he suffered no dreadful contusion of his body, nor any ill effects at all appeared. This case was very remarkable, as the wound was so shattered that Mr. Crampton, of Glasgow, was under the necessity of removing the whole of it. The patient recovered in three months. From the foregoing I think I can believe that the arterial injury did not ensue until after the accident. The young man was taken to the assistance of St. Bartholomew's Hospital, quite well.

One curious effect occasionally follows gunshot wounds, but I do not pretend to understand the rationale of it, viz. inflammation and suppuration of unconnected parts, especially of the liver. Mr. Richardson classifies contusions, those the effects of contusions arising from local injury, and contusions arising from striking the middle of the irregular portion in the vascular system in which that system they give rise. He is also of opinion that an explanation of the subject may be deduced from the principles laid down by Mr. Harvey. (*See Med. Cas. Trans. vol. 14, p. 304*.) and Thomas, *Journal* concerning Constitutional Inflammation, Nov. 1825. Several cases of the above nature are related in the *Mem. de l'Acad. de Chirurgie*, and according to Mr. Gosselin many patients in the Division who had extensive vascular aneurysms for gunshot wounds were cured by application of their large artery. &c. (*On Gun-shot Wounds of the Extremities*, p. 14, *et seq.*)

From the circumstances of the liver extending of gunshot wounds being more than 40, less seldom, they are less of it. When the ball has fractured a bone, which fracture has occasioned great injury of the soft parts, independently of that caused immediately by the ball itself, the inflammation will have an as quick an exit as cases of contusion fractures; because the fractured part leaves no room for the formation of coagula in general. (*See* *Med. Cas. Trans.* p. 325.)

From the same circumstances of a part being very vascular, gunshot wounds frequently cannot be completely understood in the first instance, as it may seem it is at first impossible to know what parts are killed, whether bone, tendon, or soft part. Not seldom in such cases the wound separates, much often upon the wound. I have experienced that was previously

noticed. For myself, some vision, and part of some cases, or a part of some large artery, or even a bone has been killed by the violence. If a piece of intestine has been killed, the contents of the bowel will begin to come through the wound with much force. If a portion of a large blood-vessel is killed, a profuse and even fatal hemorrhage may ensue, when the stump is detached, although the material quantity of blood may have been previously lost. (*See* *Med. Cas. Trans.* p. 325.) Thus, several days after the receipt of the wound, and when all danger from inflammation is over, a bleeding peritonitis, occasioned by the separation of a stomach from some internal vessel, may destroy the patient, as happened in a very interesting case recorded by Mr. Gosselin. (*See* *Med. Cas. Trans.* p. 325.)

A soldier of the 21st Regiment of the 54th Highlanders was shot in the foot at the battle of Bergen-op-zoon in 1814. There was no hemorrhage for ten days; but at the end of this period the popliteal artery gave way, and I was obliged to take up the fractured artery, by which means the bleeding was effectually stopped, and the man recovered. This fact, and another related by Baron Boyer (*Annuaire Med. Chir. de Paris*, p. 356, *et seq.* Paris, 1813), prove that a ligature on the femoral artery may satisfactorily check the current of blood through the popliteal artery to put a stop to hemorrhage from a wound in it; and though such pressure is some way from of wasteful pressure is sufficient to arrest the flow of the artery, with which the blood passes through the anastomosis into the part of the wound below the ligature (*see* *Med. Cas. Trans.*), its general causes in gunshot wounds of the foot, would be of infinite advantage, not only as a means of the difficulty of taking up the fractured artery, but its definiteness only defined by the fact, but by a ligature upon the artery and divided parts would frequently have been lost. At the same time I would have suggested always recollect that the important difference between an anastomosis and a wounded artery; for as in the first case there is no real rupture of the vessel, the transmission of the blood into the part of the vessel below the ligature may keep a patient in the hands, but is attended with no risk of hemorrhage; while the same free passage of the blood into the wounded portion of a large artery would give rise to dangerous bleeding; and hence the general necessity of applying two ligatures, one immediately above, the other below, the opening in such a vessel. A single ligature on the brachial artery, as I had an opportunity of seeing at London in a case of gun-shot wound, where rather than vessel of the continuation of the radial or ulnar gave way, on the loosening of the ligature, and, as there was considerable swelling, edema, and inflammation of the hand, threatening gangrene, the surgeon under whose care the patient was desired it right to perform amputation.

I should be sorry if these observations were to hold out any general expectation of the great and dangerous practice of applying only one ligature above a wound in a large artery, as in any recent case of false arterial aneurysm. The aneurysm delivered above were chiefly intended to refer to gunshot wounds of the leg, great artery of the popliteal artery, and hemorrhage first breaking out several days after the receipt of the wound, when all the parts below the knee are enormously swollen, and in a state of inflammation and suppuration. Here the hope of avoiding any additional violence or injury of the damaged parts below the knee may be a good reason for taking the chance of stopping the bleeding by a ligature applied to the femoral artery; a reason, however, which would not exist in the case of a recent wound of the popliteal artery with a bone. At the same time I believe the chance of checking the current of blood will not always suffice, and that occasionally early the dangerous symptoms of effusion upon the swelling in the damaged state of the leg, and of applying a ligature above and below the aneurysm in the popliteal artery, must be applied to the aneurysm, or suppuration perforated. When the first plan has answered in some cases, and not in others, may depend upon the size and condition of the wound or opening in the artery, and, as examples of clamping upon the degree, at which the risk of the vessel may have been closed by the influence of inflammation. When a conclusion may now have been made respecting the risk of the vessel being wounded or opened, while in fact only a branch of it

to contend with these casualties, as while the possibility of openings has been made by different bullets.

As a soldier writes his acquaintance, "It is an experience thing for a ball, in striking against the sharp edge of a bone, to be split into two portions, each of which takes a different direction. Sometimes it happens that one of the pieces remains in the place which it struck, while the other continues its course through the hole. I've hit with the side of the pistol, I have known one half pass through some member of the body, and the other remains in the joint or mortis, without its previous trace being suspected. In one case, however, I have seen a ball divided by striking against the spine of the scapula, and one portion of it pass directly through the chest, from the point of impact, while the other moved along the interspaces, till it reached the diaphragm. But the most frequent examples of the division of bullets which we had occasion to see, were those which were produced by balls striking against the spine of the scapula or the scapula, sometimes happen, that one portion of the ball strikes the vertebra, while the other either remains behind, or passes over its external surface. Not infrequently, in all cases of the entrance of balls are lodged between its two tables, in some instances both fractured and shivered in these strips, and in other instances without these bones being changed." From these facts it must be evident, that when a gunshot wound has two entrances the surgeon cannot be certain that the bullet has not been divided, and that penetration is deeper, than the entry ball just happens to be found. (See *Thomson's Disc. on Military Hospitals in Belgium*, p. 27, &c.)

As the study of the facts would be combined and comparatively gunshot wounds have at first been generally considered, and most other wounds, unless there is a hemorrhage, happen to be injured. In the beginning, there may even be little hemorrhage, though a considerable injury is so often, and a hemorrhage is a dangerous and often bleeding injury. Thus, (as I have already mentioned), in one of the wounds of the chest, which I received a gunshot wound through the lung, the physical injury was very slight, but after the injury, and compelled me to take the antiseptic injury, and in the Hospital at Brussels, I received the wound under the care of my friend Dr. Giller and myself, about a week after the battle of Waterloo. The case of hemorrhage, on the lowering of the strength, were tolerably common, not at all surprising with a more calculation, that the presence of such elements, require the figure of a man, as very three or four in 1000. (See *Thomson's Disc. on Military Hospitals*, p. 5, &c.) In Belgium, the case of Dr. Hutton's observation upon this point appeared to me to be completely confirmed.

It has long been known, that a bullet may be lost by shot off, even after it has struck the body, and hardly any hemorrhage arise. We had numerous proofs of this, but after the battle of Waterloo. I had made my case a man of the rifle brigade, whose arm was shattered to pieces at least as the shoulder, yet there was no hemorrhage. I sympathized the high of a British soldier whose leg had been completely shot off by a cannon ball, but there was no hemorrhage before the operation. At Mauthausen, in 1814, I saw a case of the great part of the right arm, and many adjacent parts had been carried away by a cannon ball, and yet no bleeding of consequence occurred.

Sometimes, after these violent injuries, the large arteries do not find interruption. "We saw a man (says Dr. Thomson), whose leg had been shot off by a cannon ball, in amputating the leg above the knee, the arteries of the thigh were not perceived to bleed; nor did any of them afterward require to be tied. A considerable loss of blood followed itself, in which the arm had been shot away close to the shoulder joint."

Sometimes the common, produced by a cannon ball, or the passage of a bullet in the vicinity of a large artery, results in some enlargement of the upper part of the vessel, and a subsequent dilatation of its body by the effects of sympathetic lymph. This is proof of this statement are recorded by Dr. Thomson. (See *Thomson's Disc. on Military Hospitals in Belgium*, p. 21, 22.)

Artificial, however, bodies, such as pieces of iron, lead, &c., produce the same dangerous wounds than usual gun bodies, the leaden bullets. Wounds occasioned by a small shot are frequently more perilous than those produced by larger balls; because their

track is so rapid that a bullet is traced, but can scarcely the entrance body most extensive. Such a shot often injures a vessel, which there is not the slightest external evidence of the entrance. Sometimes a great part of the danger also comes from the motion of the bone which has been struck.

REMARKS ON THE TREATMENT OF GUNSHOT WOUNDS.

The first thing in the treatment of a gunshot wound in one of the extremities is, to determine whether it be most advisable to amputate the limb immediately, or to undertake the cure of the wound. When a bone, especially the joint, is very much shattered, when the fleshy parts, particularly the great blood-vessels are severed, are lacerated, when the whole limb has suffered a violent contusion, and is cold and senseless, there is no hope of preserving it. In this case, it is the surgeon's duty to amputate at once, and not to delay till inflammation, fever, and tenderness, to mortification come on. But besides this violent degree of injury, in which the possibility of amputation is obvious, there are several lesser degrees, in which it is often a difficult thing to decide whether the operation is necessary or not. Then the surgeon must look not only to the injury, but to the patient's constitution, and even to external circumstances, such as the possibility of procuring good accommodations, rest, attendance, and pure air. But it is especially to be considered the necessity of amputation by general rules. In every individual case, the surgeon will consider mutually the particular circumstances, before he decides to decide. The grounds against any operation are, the pain which it causes at the period when the whole system is disturbed by a terrible injury; the operation of a limb, and frequent amputation, in which cases, aided by judicious surgery, repairs the most terrible wounds. The following are the reasons in favor of the operation. If the patient gets out of a frightful condition, which threatens an increased pain, and which is increased as it were, for a simple wound case. The pain of amputation is not of more instant than the pain which the wounds last cause, and the extraction of foreign bodies would cause in case the operation were abandoned. In case of gunshot wounds, the loss of the limb cannot be taken into the account; for the surgeon only undertakes the operation when he designs to save the patient's life by that operation, and acknowledges that the part itself cannot be preserved. Even if he should despair, the patient of a limb, that perhaps might have been preserved, there is this statement, that he can furnish last with an artificial one, which often proves to be more serviceable than the one which would have proved, had it been preserved. Should the operation be found to be so indispensably performed above the wound.—(See *Thomson's Disc. on Military Hospitals*, p. 1.)

When amputation is deemed necessary, the surgeon, according to several firmly as regards, is to divide the vessel by one or more incisions. Many of the modern weapons employed by the surgeons, when directed into the body, instead of incisions before they could be entered; and this was the case, not only with regard to the arms, but also with regard to the use of stone, pieces of iron, and leaden bullets, which were thrown by means of slings. Unless surgeons the necessity of cutting to the vessels, through which these bodies had entered, and may therefore be justly regarded as the first and most necessary of the practice of division in the treatment of wounds made by gun bodies.—(See *Thomson's Disc. on Military Hospitals in Belgium*, p. 28.)

Such division has been said to have numerous advantages; to facilitate the extraction of foreign bodies; to produce a typical healing, and afford an opportunity for the amputated limb in the circumference of the wound; to prevent the formation of the track of the ball, by an open wound; and, lastly, to divide ligaments, arteries, and veins, which otherwise might give rise to sympathetic and other untoward symptoms.

More modern experience proves, however (Götte, p. 629), that the utility of such incisions has been overrated; that they generally increase the inflammation, which in these cases is so much to be apprehended; that wounds which are not dilated externally heal more speedily than others which are; and that there are only a few cases in which incisions are beneficial. In fact, as Dr. Hennen has correctly stated, the knee

is now rarely, if ever, employed in the first instance by English surgeons, except for the purpose of ascertaining the nature of the wound, and other extraneous bodies, or for facilitating the application of ligatures to bleeding vessels.—(*See Principles of Military Surgery*, p. 44, ed. 2.)

The apparatuses from the practice of dissection—viz. the *trachea* (Trachea), were very early pointed out by Galienus; and it is singular how much the opinions of this author, with regard to the point in reality surgery, coincide with those of Mr. Hunter.—(*Op.*, vol. p. 46.)

The causes of gun-shot wounds are various. Sometimes the track of the ball goes superficially under the skin, and only has cut opening.—When it goes in and out, and the ball has perforated a bone, and a considerable blood-vessel, all injuries are serious, for the wound here cuts off the arteries. Though dissection the wound has been practised with a view of giving vent to matter, excreta, and foreign bodies, and even its whole track has been laid open when superficial, an experience proves the reality of such things. As when a ball has passed with great force there is often a real line of resistance in the skin, a portion of which is driven forward before the ball, it follows that the opening of a gun-shot wound must be more extensive than that of a punctured vein. By the separation of straggles, the wound becomes still more dilated, so that not only matter, but foreign bodies which approach the skin easily find an exit. Besides, incisions commonly close again very soon, and in a few days the wound falls into the same state as if no alteration at all had been made.—(*Hunter*, p. 303.)

Ligaments, fibres, and vessels are often situated about the orifice of a gun-shot wound, and some surgeons have made it a rule always to divide them completely; but, when the vessel is injured, the tearing and contusion of parts should cause violent spasms and nervous symptoms, and should be regarded the discharge of matter and foreign bodies.—When they discoverly raise the first efforts, the propriety of dividing them cannot be doubted; but with a mere exploration of the orifice I consider the practice unnecessary. Here, as Mr. Hunter wisely remarks, the method would be very good if wounds and fractures were such a source of wounds, as it is now to be proved that the effects of dividing a part that is already wounded were different from those of the first wound; but the employment of the knife being only an extension of the first incision, it is to be considered as common sense, and common observation.—(*On Gun-shot Wounds*, p. 331, 332.)

The extraction of foreign bodies works as one of the most urgent motives for the dilation of the wound, and no doubt it is right to remove as first as may be those as possible. Their removal prevents the wound, causes violent spasms and inflammatory symptoms, and causes suppuration; suppuration which the timely extraction of them may prevent. Yet let it be remembered that the extraction of foreign bodies is frequently attended with excessive irritation, and that, while they lie too freely fixed in place, it is often a matter of impossibility. After the clots have appeared, and the wound has become widened, suppuration frequently does not prevail long before the extraneous substance becomes loose, spontaneously separates, the skin, and easily admits of removal without any difficulty.

Hence, it is generally prudent to attempt at first only small foreign bodies as we near the external opening, gentle, and removable without much inflammation; or such as pass on parts of the surface, and thereby cause dangerous symptoms. The surgeon should avoid interfering with those which are deeply and firmly lodged in the wound. He should avoid suppuration, and the detachment of straggles, and when the foreign bodies become movable and apparent, he should extract them with or without an incision, as various stations may demand. The removal of the wound ought to be made as early as possible with the finger, which increases less, and does not cause distress, and a good. A great variety of instruments have been devised, either for ascertaining the position of balls and other foreign bodies in gun-shot wounds, or for extracting them. But however ingenious and diversified the contrivances may be, they all stand in being divided into three kinds. The first consists in the principle of a pair of forceps, others are shaped more or less

like spoons; and a third description are made in the form of a cork-screw or worm. These last are only designed for cases in which the ball is fixed in the substance of a bone, and is quite immovable. For if a wire is lodged in the soft parts, this position requires for introducing the wire into it would cause an inflammation of the parts in the interior of the wound. Barretraves, constructed in the form of *serpents*, into the groove made at not being adapted for entering the soft tissue, their heads are expanded, which always causes the wound, and causes a great deal of distress. Persons have been destroyed with blades which may be introduced separately, and then joined together with a wire. When a ball lies superficially, the fingers are a sufficient means of extracting it, being introduced, and with respect to indolent wounds, as Dr. Hunter has justly observed, they are completely unnecessary in the common cases, or that of *Barretraves*, though unfortunately the art of instruments is most abused in treating deep wounds where we are told that the use of them.—(*Principles of Military Surgery*, p. 76, ed. 2.)

The extent of the wound does not necessarily indicate its severity. Extensive wounds appearing in the vascular portion probably, as some have been led to be easily recoverable, or they continue to increase, prevent the cure, and give birth to a suppuration. In some instances, the wound closes, and the blood is retained in the skin during the wound remains, and in other cases after a time they bring on a suppuration of the surrounding parts. Sometimes a foreign body remains in the wound, and after a time, and afterwards making its appearance in a different part, where it may excite inflammation and suppuration.

When the ball enters in the wound, it is better to thrust it in, as the parts collapse after its passage, and make an opening in the skin which would not be the ball itself. The ball does not generally enter a straight direction through the wound, but enters a very tortuous one, particularly when the ball is badly shaped. In every case in which it is not clear that vessels of the wound are exposed, it is better to leave the wound as it is, and let the blood flow out, and the first intention to cure.

Remember the ball may be both easily and safely removed. At such times it becomes the surgeon's duty to be quick, and to be sure. According to Mr. Hunter, if the fragments under which the ball is lodged should be so situated that they were getting through, they are to be considered as already split, and no opening is to be made in them for the extraction of the ball. But when the ball lies in a situation where the skin that it can only be for, and the skin over it is quite unbroken, no incision opening ought to be made. The wound heals better when the ball is left in, and for less inflammation takes place in the recovery of the extraneous body than when the orifice of the wound. A counter-opening always renders the inflammation of the bottom of the wound as great as at first. It is better to let the wound heal up, and extract the ball afterwards.—(*See Hunter*, p. 333.)

To the practice of this Mr. Hunter has no objection, who seems to be that he has not seen a great number of balls which were not more than an inch from the surface, and never found any suppuration arise. But when the ball lies three or four inches from the surface, and being so distant, he is then that its removal should be first made with the eye of extracting it.—(*On Gun-shot Wounds*, p. 33, 34, ed. 2.)

Sometimes the ball penetrates the wound just at a bone, and follows freely in it. When a wound is formed superficially, if any substance is introduced and introduced by means of an elevator with a skin and what curved necessary, and when it is found that the ball is deeply lodged, and will not move, it is to be removed. Should the attempt be the appearance of a fungus on the wound of the ball is recommended by some writers; while others, finding the process difficult, and afraid of such an operation, and not feeling that balls have sometimes remained for a long time for many years without any serious consequences, content themselves with the last remedy. Mr. Hunter says it does not as a general rule, subject to a few exceptions, that a ball shall never be allowed to remain in a bone; he says he, "if a ball lodge in the head of a bone, and is not removed, it generally causes death of the bone, disease of the right, amputation, or death." In this case of a long bone, however, the last part

allows, with masses and jets of matter. On a hot bone cavity is equally the result, and if it is surrounded by large vessels, various jets in various directions, contractions of the hot take place, and the gullet drags on for years, wastes of life, and ready to submit to any thing to obtain relief.—(On Gun-shot Wounds, p. 20, ed. 1.) A mass of these cases are given in terms to be considered, however, that the pressure, absorption, and various action the effect of the movement of the ball, that of the vessels, logically accounted for the parts injured which it has struck. All medical forms latter only assist the attempt to remove balls with a slighter when they actually produce dangerous effects.—(Ibid. de Cline, M.D., 4, p. 100.) I am disposed to believe that whatever the situation of the ball is, whether it has been removed or not, from a case with tolerable continuity, and without too much infection, the practice is commendable. This branch of management of gun-shot wounds appears to me still to require further elucidation, for though experience has been abundant, the right effect and quantity of particular are yet laid down in the best possible way.

As soon as the requisite conditions are ready, and danger has been eliminated, the primary object is to treat most of gun-shot wounds are accomplished, and the rest is, in reality, the different view the variety of other wounds.

With regard to putting gun-shot wounds; when it is evident that the shot has passed over, and no particular object can be fulfilled with the probe, it is either better to disfigure with such exactness, as to leave all necessities but none. Introducing any instrument is generally disadvantageous and painful irritation. But when the ball or any other extraneous substance has lodged in the wound, and its situation is not immediately evident, it will often be advisable to search for it in order to see that it may be extracted, if its situation will allow, before inflammation begins. The surgeon, therefore, notwithstanding the common view, cannot turn to leaving it impossible consequence of the nature of the wound, rather give a probe that penetrates to some extent, he thinks more likely to pass readily along it, and avoid then, proceed to make the extraction. But when this is very painful, and the course of the wound obvious, it will often be better to dissect, and remove the search when suppuration has taken place, in which case it can be undertaken with more ease and a greater prospect of success. When gun-shot wounds are ordered, the tenderness and swelling of the parts are particularly strong reasons against painful probes, as efforts to extract foreign bodies as long as this state lasts.—(On Gun-shot Wounds, p. 27, ed. 1, vol. 2.)

There is no doubt in the practice of surgery better concluded that the dressing of narrow scale and gun-shot wounds with lint is particularly harmful. The only possible reason for doing so is the latter cases must be to keep the surface of the wound from healing up, and disfigure extraneous bodies, unless, &c. The application of this happening at first is quite inadvisable; for the inside of the mouth of the injured part is often lined with a slough or scorch, which need necessarily be removed before the parts can heal. The first dressing, therefore, should be with something soft, and of a mild, soothing nature. On the ball of the foot, indeed, it would be well for safety of the wounded, if the stump were to be coated himself with a soft, simple dressing, and covering the part with linen wet with cold water. This method would prove much more healthy than the hairy and cottonaceous use of absorbent clothes, wadding, and such waddings, from the bad effects of which thousands of soldiers have lost limbs or lives, which, under more judicious treatment, might have been saved. Having used to varying, sometimes, plasters of simple liniments, and frequently over the latter an excellent powder. In the suppurative stage of gun-shot wounds poultices are generally allowed to be the best applications.

Proceeding thus, since I cannot altogether approve the following directions, though they are certainly better than any given in many original books. "A small bit of each lint may be placed loosely between the lips of the wound, in order to keep it from closing. It is unnecessary, it should be introduced a little beyond the lips, in order to exclude all fluids off and, and to prevent irregular collection from flowing over the surface during the supplicative stage. As those

would keep the direct exit of the discharge. For the wound is not to be closed with lint, which has been showed with it. A pledge of some simple material being then laid on with care or cloths to secure the discharge, and those prevented from coming off by a bandage loosely applied, the patient may be put to bed, and so placed, if possible, as to keep the centre of the wound dependent."—(Quercus, p. 185, 186.) The reason for what I consider objectionable, namely, introducing lint in first dressing the wound, was no doubt to avoid cohering.

In considering the effects of position and cold application upon gun-shot wounds, Mr. Graham remarks a learned and judicious in the use of cold water.—"The inflammation is, in some instances, exceedingly prevented in many greatly controlled, and in almost all, very much subdued by it, with the suppurative process is not stopped, in the quantity of cases, or in degree sufficient to interrupt the subsequent act of granulation. In all simple cases of gunshot wounds, that is to say, such wounds, in persons of a healthy constitution, a piece of lint which has been dipped in oil, or to which some balsam has been spread, is the best application at first to prevent cohering, with the view of adhesive plaques placed across to make it in its situation. A poultice, or some kind of dress wetted with cold water, or when to be applied over it, and kept constantly wet with oil, even by the use of oil, if it can be obtained, and be found comfortable to the feelings of the patient. A roller is of service, to keep it from the compression from changing the dressing along, and is, therefore, at that period most useful as a surgical application it is useless, if not positively injurious, because it hinders a part which ought to be a certain extent to swell, and by pressure causes irritation. However gentle it is to be applied immediately after some days have elapsed, and it is impossible to keep it there in the face of heat, even if they were useful, some warm poultice is to be kept in position; because, when they are applied in the first instance, they soon become stiff and bulky, and are the most painful, and are seldom present after the first dressing was to be made useful in the period when the surgical application of a water was indispensable." To this last reason of the wrong employment of rollers, Mr. Graham annexes some remarks, in which he enters into a general consideration of position, its application to gun-shot wounds, believing that, in many instances, cold water only be employed with the best effect during the whole progress of the cure. These remarks are tempered with the following observation:—"Cold water is not, however, an infallible or even always an advantageous remedy; there are many persons with whom cold applications do not agree; there are cases with whom they destroy after a certain period; and, in other cases, they should not be persisted in. Cold does no good in any stage of inflammation, when the secretion arising from the first application of it is not agreeable to the feelings of the patient; when, as then, it does no good; but if it produces a sensation of stinging, or an uncomfortable feeling of any kind, with stiffness of the part, it is doing harm, and a change to the most soothing of waters will not only prove more agreeable but more advantageous. This holds in general about the period when suppuration has taken place; and yet, in such cases, is preventing the full effect of the action which warmth encourages. Precautions are then proper; and if a position be preferred for the application by day or by night, an unobtrusive use of heat will be found sufficient. In the spring of the year, the warmth of the sun makes an excellent poultice, and so do turpentine, cataplasms, &c., judiciously of course, liniment, sweet, hyacinth, and other firmnesses and balsams. In all those cases where a position is avoided by its warmth is to be paid to the period of suffering as of applying it. It is used as a moderate poultice, softness, swelling, the numerous arising from cold, and is changing the remaining of interrupted action of the vessels towards the presence of matter; and as such as that that applied has been stated, the position should be changed, and become again had to cold water with compress and bandage."—(P. 18-27, ed. 2.) Although I fully coincide with Mr. Graham, respecting the general advantages of cold water, the dangers of tight bandages, and the bad effects of constraining positions too long, I do not coincide in

many of the symptoms which he has expressed about these last treatable suppurations. On the contrary, I appreciate that in the best means, whenever a thought is to be thrown off the matter is decidedly fitting, and in these efforts are very frequent in cases of gunshot wounds, my own opinion of the utility of cold applications is limited to the first three or four days after the receipt of the injury. Nor ought cold applications ever to be continued where the temperature is low, and languid circulation in the part induces a risk of gangrene. Hence, when a principal artery is lacerated, its employment is always wrong and hazardous. At the same time I have no hesitation in declaring my firm belief, that fifty times more gunshot has been done by tight rollers applied to recent gunshot wounds, than by either position or cold applications.

Further, when the track of the ball has two apertures, a scar is sometimes drawn through it, with the view of preventing a secondary discharge of the wound, and introducing proper applications. The scar is also supposed to give free vent to pus, and to promote the evacuation of foreign bodies. But a gunshot wound is better left open to close granularly, and while a scar rather obstructs the exit of pus, it may as easily push foreign bodies more deeply into the track, as out of it. There are preferable modes of applying the necessary remedies, and as a rule in an extensive substance itself, its employment cannot fail to be highly pernicious.

Gun-shot wounds generally require the employment of antiseptic means, just as other wounds attended with equal inflammation. When they are in the undrained state, the application of leeches is highly proper. In these cases bleeding is recommended, and in such a measure as if it were of more service in these than wounds in general. But the necessity for the operation is really not greater than in other wounds, which have done the same degree of mischief, and from which the same quantity of inflammation and other symptoms are expected. Bleeding is certainly proper here, just as it is in all controllable wounds attended with a severe, fat fatal, and great chance of extensive inflammation, and much symptomatic fever. In every instance, however, the practitioner must take some care not to be too long in the practice of bleeding; for when the patient is reduced below a certain degree, his strength is inadequate to support the large and long-continued suppurations which often cannot be avoided.—(See *Illustr.*, p. 362, 363.)

As the orifices of the vessels torn by the ball are compressed, and as a new, oftentimes, sometimes to be changed of importance is remarked in it. But as I have already stated, after some days, and frequently at a very late period, when the slough separates, violent hemorrhages may occur, which are the more dangerous as they come on unexpectedly, and often when the suppuration has already induced great debility. The surgeon himself may increase the bleeding by removing the dressings carelessly. Hence, in every case where, from the situation of the wound, there is reason to apprehend injury of some considerable vessel, the patient must be constantly and strictly watched, and every thing necessary for the immediate stopping of hemorrhage provided.

Another kind of hemorrhage, still more dangerous than the former, particularly occurs in such gun-shot wounds as have long been in a state of violent suppuration. The blood does not issue from one individual vessel, but from the whole surface of the wound, as from a sponge, and in such a manner to prevent blood and water. This hemorrhage is very dangerous, because it is particularly apt to exhaust the patient, who is already debilitated, and its causes are difficult to remove. The case demands the exhibition of bark and diluted sulphuric acid; the dressing is laid with a preparation of starch and being applied to the wound.—(See *Illustr.*)

Gun-shot wounds in trochanter military hospitals, especially when they are established in military hospitals, and the dressing is not paid to ventilation, cleanliness, and cleanliness with some cold gas, are often attended with local gangrene, a very serious and dangerous complication, of which I shall speak under the head of Hospital Gangrene.

The pain of removing the first dressings is so soon as necessary in gunshot wounds at other cases, by

creating a primitive inflammation of the parts. This observation is particularly true when dry has been used, and it is so when in the wound. When the occurrence of bleeding, severe pain, or other extensive symptoms occur, on either a different time of contact, I think such dressings should rarely be removed before the end of the fourth day. And a cold-water has not been constantly applied over the wound, so as to keep it moist, or if such has not been spread with some mild saline or digest it in it, I think it a good plan to apply an emollient poultice over it the evening preceding the morning on which the dressing is to be first changed. By this means they will be softened, and relief of being taken away without pain or irritation. With the same view, plenty of warm water should be applied from a syringe, and allowed to fall upon the dressings. Physicians at all of whom should generally be taken off under this, yet not, so they are not adherent, and in warm weather, may become moist and relaxing.

For after days the matter seldom assumes a healthy appearance; but as soon as the wounds require, a first process of a proper quality, and the wound was to be closed as a simple abscess.

Sometimes the healing process does not succeed, though suppuration has preceded a considerable time. On the contrary, notwithstanding the existence of a virus and a generous diet, the suppuration ceases to proceed thoroughly, and the wound becomes chronic, left the matter there. The bones show an disposition to move, and the patient, ordered by local dressings, is really approaching suppuration. In this case, the any suppuration is preserved by antiseptic dressings, but without result. We ought never to be deterred from undertaking the operation in the later and unclean, which frequently even disappear when the best means is resorted.

OF APERTURES IN CASES OF GUNSHOT WOUNDS.

The 21st volume of this Dictionary, published in 1814, contained all the valuable observations of Baron Larrey, of former of military surgeons, in every instance in which the operation is considered judicious. Since then, the policy has been formed with several good practical books, in which the necessity and necessity of early or immediate amputation in such cases are largely treated, and the work of the doctrine is illustrated by additional facts. It is to be observed, however, that the early too hasty plan (as there have always been some advocates in the military practice. "The Doctor says Dr. J. Thomson) is the last written on military surgery, in which works I have found the professional attention in the severe cases of the extremities; and it is worthy of remark, that he directs the operation to be performed before inflammation and other constitutional symptoms shall have supervened.—See *Traité de la Cure radicale et permanente des Amputations*, par J. de la Croix, Paris, 1812, p. 313; and Thomson's *Report*, &c. p. 181. Whether not only recommended and practiced immediately amputation, but the same thing, was not unfortunately done by the military surgeons of his time.—(See *Report*, Thomson, by R. Thomson, 3d ed. Lond. 1826, p. 413.) The celebrated Dr. Price, in the excellent little treatise of military surgery, declared himself an advocate for immediate amputation in all cases in which that operation, when first, appears to be indispensable. Le Dr. Price has in the same time stated briefly, but most judiciously, the circumstances of all cases of this practice, with those which may be expected by delay.—See *Traité de la Cure radicale et permanente des Amputations*, par J. de la Croix, Paris, 1812. Early, who has argued against the late of Le Dr. Price, with regard to the utility of immediate amputation. In order to give some idea of the necessity of amputation, early proposed that the surgeons, during battle, should be allowed to remove limbs, and amputated in the rear of the army.—See *The Method of Treating Gunshot Wounds*, by J. Early, vol. 2, p. 25, London, 1814.

After the battle of Waterloo, in the year 1815, the Royal Academy of Surgery in France adopted a vote for the best dissensions in the gunshot injuries requiring immediate amputation, and in other cases of the same nature, where the symptoms, though deemed la-

erately, might be delayed. "L'expectation d'une opération chirurgicale dans les plaies compliquées de fractures des os, et principalement celles qui sont fracturées par armes à feu, détermine-t-elle ou non le fait d'une amputation, ou le danger, et le danger si imminent de la laisser, et en l'absence des causes?" The first was adjudged to be the question of M. Pature, the main object of whose paper was to demonstrate delaying the operation. The sole of the question proposed by M. Pature has found some modern advocates of degenerated talents and valour, such as it is between the camps of Russia, France, Prussia, and Lombardy. It is, however, only justice to M. Pature to state in this place, that though he required immediate amputation as that of danger, he admitted that there were some kinds of injuries of the extremities in which it was inadvisable and immediately required. "The circumstances," says Dr. Thomson, "which may rather be given of these injuries to leave still and distinct than any which had been published before his time. And, what may appear strange, it does not differ, in any essential respect, from the amputation given by later writers, who, in combating his opinions, have appended him as an enemy to amputation in almost all injuries of the extremities."—(*See Report of the International Conference of the Military Hospitals at Berlin*, p. 152.)

By 1740, Baron Percy, who was a few years ago at the head of the medical department of the French army, published a book, in which he gave a preference to delaying amputation as first, even in cases where it is certain that the operation, once performed, will be demanded.—"See *Mémoire de Chirurgie et de Médecine*."—Even as late as 1806, Landolt, professor in the Military Academy of Strasbourg, defended the doctrine of M. Pature.—"See *Chirurgie des Blessures des Membres supérieurs* par J. Landolt."

Although in France the Academy of Surgery thought proper to determine prior to M. Pature, whose doctrine thus received the highest approbation, yet in that country very opposite limits were set to its more quiet and contingent nature, and extensive military practice. Thus, Le Doyen, consulting surgeon to the French army, in his work on gun-shot wounds, published in 1720, expressly states, "that when the amputation of a limb is indispensably necessary in the case of a gun-shot wound, a ought to be done without delay."—(*L'opérateur*, v. 1.) Dr. La Marquière is particularly wise in his excellent observations in reply to Blandin's arguments which, I think, would do honour to the most accomplished surgeon of the age in which we live.—"See *Mémoire sur l'Expectation dans les Plaies de Brûlures, et dans les Plaies de Chirurgie*," t. II, p. 1, 104, in (1786.) M. Boucher, of Lisle, was an advocate for the same side of the question.—"See *Observations sur les Plaies de Brûlures et de Médecine*," t. I, p. 1, 104, in (1786.) Blandin, who was many years surgeon-general to the Prussian army, published in 1770 an essay on amputation, in which he is particularly rigorous, that during his stay at Paris, in 1738, the surgeons of the Hôtel Dieu had been in the habit of performing extensive amputation in severe injuries of the extremities. He also declares himself as adequate for operations immediately in all cases, in which amputation from the first appears to be necessary, and insists, in a particular manner, on the increased danger which he had seen arise from the disease during the second period. He gives this life, J. Thomson has inserted a minute and circumstantial description of these injuries, both of the upper and lower extremities, in which he considered amputation to be necessary, and in many of which he had actually performed it with great success. Blandin's opinion is Dr. Thomson to have given a better account than any preceding military support of the efficacy of the ligature; and even the results of his experience, he was led to believe, that though compound fractures of the lower part of the thighbone might, in favourable circumstances, be cured without amputation, yet that this operation is particularly necessary in all cases in which the fracture is situated on, or above, the middle of that bone.—(*J. L. Thomson, Traité de Chirurgie Militaire*, & J. Blandin, 1780.) With the foregoing arguments we have to join one of not less authority, namely, that of Baron Larrey, who has proved this so convincingly, that when amputation is to be done in cases of gun-shot wounds, nothing is so pernicious as delay.—(*See Mémoire de Chirurgie Militaire*, tom. 2, p. 454-455.)

It is further to be remembered, that the principles

declared by Baron Larrey are, in point of fact, the same as those which were so strenuously advocated by Mr. Pott, whose principal remarks on the necessity of amputation in certain cases are contained in another part of this publication.—(*See Amputation*.) Mr. Pott, indeed, was not an army-surgeon, and what he says may not perfectly be designed to apply to military practice; but he has, represented, as well as any body can do, the necessity of immediate amputation in cases in which there are doubts that amputation cannot be dispensed with.

Mr. John Bell, among the moderns, appears to hold Thomson to have been right by the above manner as which he defended the necessity of early amputation, long before the contents of later writers were ever thought of. He distinctly says, that amputation should, in those cases where the injury is clearly and irreversibly done, be performed upon the spot.—(*See Thomson on the Fracture of the Femur*, &c., of Wounded, p. 69, 182, 23.) In short, notwithstanding all the military professions in vogue upon this interesting topic, we must acknowledge, with Dr. Thomson, that the primary in favour of the advantages of immediate amputation, and of early amputation was that of the army.—(*See Report of the Conference of the Military Hospitals at Berlin*, p. 152.)

The strongest body of evidence upon this point is undoubtedly afforded by Baron Larrey, whose situation at the head of the medical department of the French army afforded him most favourable opportunities of judging from actual experience. "Upon this subject," says he, "more than thirty years of continual war have afforded me an opportunity to the highest pitch of perfection, there can be no mistake." It is after having repeatedly compared the medical systems at this time, it is worthy of remark, and beyond all question of the army, that I proceed to discuss the different opinions delivered in the hospitals, and to settle definitely this great question, which I regard as the most important in military surgery.

If we are to decide that the amputation of a limb is a great operation, dangerous to the consequence, and always prevent of the patient who is thereby disabled; that, consequently, there is more danger in doing a limb, than in cutting it off with despatch and ease; these arguments may be refuted by answering, that amputation is an operation of necessity, which admits a change of preservation to the extremity, whose death appears certain under any other treatment; and that if any doubt should exist of amputation being essentially indispensable to the patient's safety, the operation is to be deferred, all nature has declared herself, and given a positive judgment for it. We are also justified in adding, that this plan of preservation is at the present day much greater than at the epoch of the Academies of Surgery. We learn from M. Pature, that of about three hundred amputations, performed after the battle of Fontenoy, only thirty were followed by success, while, on the contrary (says Baron Larrey), we have since seen more than three-fourths of the patients on whom amputation has been done, and some of whom were but two limbs removed. This improvement is ascribed by Larrey, 1. To our now knowing better how to take advantage of the advantages and disadvantages, time, for amputation. 2. To the better method of dressing. 3. To the mode of operating being more simple, less painful, and more expeditious than that formerly in vogue.

To the preceding authorities against delay in amputation, in cases of gun-shot wounds, requiring amputation, I have to add Mr. Goussier, Deputy Director of military hospitals, whose opportunities of observation, during the time, was at Lyons, were particularly extensive. In his work he has detailed the opinions of many military surgeons and French surgeons, respecting the propriety or impropriety of the doctrine of immediate amputation, and he has introduced some great criticisms, particularly on Blandin's statement of the success which was experienced in the Prussian hospitals from not performing the operation. Mr. Goussier, however, does not recommend amputation to be more immediately, if the patient be particularly depressed by the shock of the injury, directly after the removal of a piece of shrapnel, which, I believe, has already been in all times followed, not only in respect to amputations in cases of gun-shot wounds, but in other severe local injuries. "I believe it to be," says Mr. Goussier, "a stretch of theory in those surgeons who consider that if the limb injured the day in all cases, the patient would have the best

disorder of memory. No one will deny that if the dog performed a regular navigation, it would not be better than to have it do so automatically; but if they were to say the operation should in general be performed automatically after the injury, I can only oppose it because facts do not stand, and the essential point of my objection, namely its desirability in view of allowing the first moments of agitation in good sense, before any thing be done, is a point entirely foreign from that to use, etc., or right here, according to the difference of conviction and the different opinions that have been stated. The *opus*, and its three books will at most pass by brief criticism. In the first volume (Paris, 1828, and 2, 1831, 1833). In the first subject of this gentleman's book, the author's want of precision, rather than of exactness, is very apparent in the terms of this which should equally be allowed to transpire between the faculty of the injury and the performance of navigation; but still all the information is convincing that this point, though there is little to fight about, is more rather a question of method than a difference of opinion. All will know the advantages of doing the operation immediately, when by interest it not only and expressed by the shock of the accident; all kind too, prudently or otherwise, the use of little knife is more reasonable; the consequence has involved sufficiently to be capable a genuine use of the book. (See A. V. Hestrich, 1834, 1835, 1836, 1837, 1838, 1839, 1840, 1841, 1842, 1843, 1844, 1845, 1846, 1847, 1848, 1849, 1850, 1851, 1852, 1853, 1854, 1855, 1856, 1857, 1858, 1859, 1860, 1861, 1862, 1863, 1864, 1865, 1866, 1867, 1868, 1869, 1870, 1871, 1872, 1873, 1874, 1875, 1876, 1877, 1878, 1879, 1880, 1881, 1882, 1883, 1884, 1885, 1886, 1887, 1888, 1889, 1890, 1891, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, 1900, 1901, 1902, 1903, 1904, 1905, 1906, 1907, 1908, 1909, 1910, 1911, 1912, 1913, 1914, 1915, 1916, 1917, 1918, 1919, 1920, 1921, 1922, 1923, 1924, 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 1958, 1959, 1960, 1961, 1962, 1963, 1964, 1965, 1966, 1967, 1968, 1969, 1970, 1971, 1972, 1973, 1974, 1975, 1976, 1977, 1978, 1979, 1980, 1981, 1982, 1983, 1984, 1985, 1986, 1987, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1995, 1996, 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456, 2457, 2458, 2459, 2460, 2461, 2

As to the emergency case, when the proximity of attention is indicated, all delay is improper, beyond the short period during which the darkness necessarily strikes down the heavy eyelids. In the last-mentioned case, the most successful computers were those who in the field hospitals devoted after the arrival of the patients, or earlier, as Mr. Huxton has suggested it, with no little duty as possible. "While hundreds are waiting for the diagnosis of the surgeon, he will never be in a loss to select individuals who will suffer not at all, or but insignificantly, and after their aid, he will betray a reasonable want of science, indeed, if, in this period of suffering, he will minutely investigate the weak, the torpid, the suffering, and the determined. While he is trying his art on a few of the latter class, unaccompanied and a cardinal will soon make a change in the state of the weak or the torpid, and a longer period and more acute pain will render even the staking proper subjects for operation." (*Military Surgery*, p. 35, ed. 2.) It appears from some remarks collected by Mr. Graham, that in the Peninsula, the respiratory inn. in secondary or delayed operations, and in primary or immediate operations, was as follows:—

	Secondary	Primary
Upper extremities	11	1
Lower extremities	3	1

mother, a father, and the third, a boy. They were recovered in the hospital for the newborn in that room, which was supervised by M. Ing. Several days were suffered by virgin Anne, anesthesia was performed: not one of the infants earned.

At Monte, after the re-establishment of Frankfurt, several of the women, who had had their eyes cut, did not have to remain in the hospital. They were then forwarded, with the aid of their husbands,

As soon after the taking of the urine, two attempts, three days apart, at the hospital, 200 g. one of the foreign, the order of the trial, none or less days after the course of the infection. Both the patients died.

At Pompano, Barra-Larrey killed two seagulls, on which management had been known to feed feral dogs along the rim of the garbage dump in the center of the city of July, 1978. She had had a local dog, and the other his right leg. Nevertheless Barra-Larrey's intent, in killing her two dogs, was to rid of witness to the crime of murder.

In the month of August, 1885, two examinations of the patient, in discharging the anæsthetic, had been a kind of hot water, and all the Spout part of their body's hurt. Times were the first time in which it was in charge the gas. At the moment when they had just returned from the anæsthetic on the anæsthetic, a spirit that had been left anæsthetic, from the anæsthetic to keep the body hot, closed, set the body to powder, the material was entirely repelled by the anæsthetic, together with every thing that was wanted in front of the change. The first half of one of the anæsthetics was completely left off, between the two anæsthetics of the anæsthetic, and there was then two anæsthetics. The anæsthetic even gave the man down the back of the space of the third of the anæsthetic. The left hand of the anæsthetic was down away, together with the anæsthetic, and the anæsthetic, and also fired to a considerable degree. The anæsthetic and anæsthetic anæsthetic, and the anæsthetic anæsthetic would have occurred, if anæsthetic had not been anæsthetic performed. In one case anæsthetic was done at the wrist; and in the other at the lower third of the arm. The two anæsthetics were followed by complete recovery, although the anæsthetic was the first and close, in both the anæsthetic, first anæsthetic and anæsthetic.

Second case. When a lady, afflicted by gas-suffering, sinks a bath in with a mirror as to watch M. Sorel, violently motioned, gasped, and deeply stirred away the salt, gasping, impetuous death to be immediately performed. If this manner be neglected, all the offered parts will mean to come with gasps, and besides, as Larrey has explained, the accidents which the gravity of the first case produces will also here be excited. It is only doing justice to the memory of M. Ferno to state, that this second case was one which he also particularly considered as *depressing* the immediate performance of respiration. (See *Paris et Fernal. Rejoux* at Chirurgical, 2. 8. 224, vol. 12, 1250.)

Third one. If a similar body were to carry away a great mass of the soft parts, and the principal vessels were left of the right, for instance, without touching the bone, the patient would be in a state demanding immediate amputation; for, independently of the softness which would originate from a considerable loss of substance, the lost part is inevitably necrotic. Mr. Durell also says, "A transfusion destroying the artery and vein at the neck of the thigh, without injuring the bone, requires amputation."—(P. 283.) When, however, the femoral artery is vein is injured by accident, but, external constriction, the position is advantageous to the vessel above and below the group, is it, if the nature of the cause arises by hemorrhage. But for lesions, that which bone vein and artery are injured, amputation is necessary.—(P. 284.) With respect to bleeding from the femoral vein, as it may easily be stopped by moderate pressure, the necessity of taking any figure at all is questionable.

"An 1834-35 of the Federal artery (abductor Mr. Garrison) regarding an epidemic, administered with fracture of the bone of the lower jaw, in a proper case for immediate attention; Mr. Garrison's early patients would recover from their various ailments, even wounds, I believe, sustained the same way; and the higher the altitude is in the South, the more extensive is the mortality by Amputation."—(Garrison, On Gunshot Wounds, p. 187.)

Flower pale & green, but often the whole part of

a member, breakfasting here, she dies and tears the muscles, and destroys the large nerves without, however, touching the main artery. According to Larry, this is a fairly rare occurring immediate aneurism.

Mr. Galtie seems to coincide in this point with Latham. "If a cannon-shot strikes the neck part of a thigh, and carry away the muscular part behind, and within the great waste nerve, paraplegia is necessary, even if the bone be unstruck, &c. In this case, I would not perform the operation by the circular incision, but would pass a flap from the fore part upwards, as I could get it, to cover the bone, which should be sutured."—(Galtie, On Fractures, Wounds of the Extremities, p. 185.)

PUPP CASE. If a pupp cannot shoot or row fast has been referred, should think a consider unfairly, without producing a suitable pup certainly in the skin, an often happens, the pupp which best in action, such as the bones, muscles, sinews, membranes, and vessels may be ruptured and injured. The extent of the internal disorder is to be examined, and if the bones fractured, through the soft parts, as if they were sinews, and if there should be much in respect, both the swelling, and a sort of fluctuation, that the vessels are loosened, suppurative fluids to be immediately granted. We were soon sorry, that this is also the advice of John Perry. Sometimes, however, the vessels and bones escape injury, and the patient can support the only punishment. In the circumstances we are engaged in follow the counsel of Sir J. Martin, who recommended making an incision through the skin. By this means, a quantity of thick blackish blood will be discharged, and the practitioner must observe. According to Larrey, such an incision is equally necessary in the preceding case before amputation, in order to ascertain the extent of the mischief which the parts have sustained.

It is no such injury done to (individual) persons, that we transmute the *solidity* of many individuals, which would be a large whole attributed to the connection produced in the air. — (See Reason, Twelve *des* Phases of *Arrest* & *Flow*.)

Although, says Langer, this question has been mentioned by writers of high repute, we may easily perceive the intricacies of the inquiry, if we carefully consider, first, the direction and course of solid and liquid bodies, and their relation to the air through which they have to pass. *Sift*, the internal disorder observable in the head bodies of persons whose breath is expelled to the most advantage of their art, regulated by the *Sift*; the properties of the elastic substances, such as the integuments, cellular substance, &c., struck by the shot.

has universally agreed among philosophers, that a solid body, moving in a fluid, only acts upon a column of this fluid, the mass of which column is exactly equal to the surface which the solid body presents.—(See *Le Penseur*, sur quelques Particularités concernées les Fluides, faites par Armand de Feu, in *Mém. de l'Acad. de Sciences*, A. 11, p. 29, de 1763.)

Thus, a chrome-ball, in striking a sphere equal to its diameter, can only displace a portion of air, in the motion of three to two, compared with the size of the shot. This fact is conspicuous in its driftable and immiscibility with the ambient air, is dispersed in all directions, and concentrated with the ball mass of the hemisphere. The force of this perfect resistance amount is nothing, and not a goal can be determined that if there is the slightest velocity of movement on any part of the body, it must disperse upon the direct action of the ball mass.

Besides, if the conditions of the motion of a ball be considered, which taskmaster is known, it is shown, in an instance referable to the spanner of the instance, it will be seen that the spanner is the object against which the ball has passed before striking the object against which it was directed, will already have materially lessened the velocity of the projectile, while the motion of the object of interest be totally lost.

The different agreements which the ball describes in its course, and the structure of the skin, enable us to explain how trifling injuries are produced, without any serious rupture of continuity, and often even without consciousness. The surface communicated to the ball by the pelvis which projects it is, for a given space, reticulated. If at this distance, it strikes against the body, it makes the pain only to be more pronounced, by the sides with which it touches the skin. As the ball, after having traversed a certain distance, undergoes

in consequence of the resistance of the air, and the attraction of gravity, a change of position, and now falls on its own axis in the diagonal direction.

If the shot should strike any resistant part of the body, towards the end of its course, it will now reveal a great portion of the circumference of the part, by the effect of its curvilinear movement. It is also in this manner, observes Lamey, that the wound of a carriage wheelman passing obliquely over the thigh at hip of an individual stretched upon the ground. In this case, the wound is the same as those of which we have been speaking. The most elastic parts yield to the impact of the revolving body; while such as offer resistance, as, for instance, the bones, tendons, muscles, and aponeuroses, are fractured, ruptured, and lacerated. For the same reason, it sometimes happens that the wound is hardly injured.

At first sight, all the parts appear to be entire; but a careful examination will not let us restrain long in doubt about the internal mischief. As this wound is oblique, it must necessarily reach outwardly, because the extrusion of blood laterally takes place in the deep incisions occasioned by the rupture of the muscles and other parts, and because this fluid cannot easily find its way through the texture of the skin. Such circumstances can only be detailed by the terms.

The foregoing reasoning is supported by experience. How often, says Lamey, we see, even the ball carry away pieces of bones, such as the scapula, clavicle, or other part of the soldier's armor, without doing any other injury? The same ball, perhaps, takes off his arm, when at a time when it is closely applied to the body of his comrade, and yet the latter does not receive the slightest harm. The effect may vary between the thighs, and these members hardly exhibit any resistance at the points which are easily penetrated; the only example in which resistance occurs. In such instances, the ball wears the front of the trunk, and the fracture of the ribs is if necessary not at all injured.

Bacon Lamey then relates the following case, which is analogous to one which I saw near Antwerp, and have already mentioned in the foregoing chapter. M. Meger, a captain, standing at the front of a square of foot, in the town of the battle of Arroy, 20th March, 1793, had his right leg almost entirely carried away by a large cannon-shot, without the posterior part of his femur being so close as to possess its position, pointing the lower injury. The violent general concussion ensued, and the extreme severity of the wound, made this otherwise condition remarkably peculiar. The progress of the symptoms, however, was checked by amputation, which was instantly performed. M. Meger was then conveyed to the hospital at Louisa, fifteen leagues from the field of battle, where he got quite well.

Lamey declines relating numerous other analogous anecdotes, which he has been called upon to mention under the same circumstances. M. Baily, a captain of the artillery of the army of the Rhine, was struck by a cannon-ball, his left arm being injured, and his head severely grazed; the corner of his hat, which was placed forward over his face, was shot away as far as the crown. This officer, the side of whose nose was then torn off, was not deprived of his senses, and he was actually courageous enough to continue for some minutes commanding his company. At length he was conveyed to Lamey's ambulatory, where amputated his arm. It is almost enough the patient was well.

Lamey expresses his belief, that what nature does essentially bettered most circumstances, if attended with the smallest share of quickness, vigilance, and attention. The least delay makes the patient's situation more extremely dreadful. The internal injury of the member may be increased by the shock, by the loss of blood, by the little sensibility retained by the parts which have been struck; and, finally, by producing an accident, as already recommended.

In order to illustrate the symptoms, which he endeavored to establish in opposition to many writers, Lamey illustrates himself with the following expression.

At the siege of Bressan, two cannon-balls, having nearly equal weight, were brought down the trenches to the ambulatory, which Baron Lamey had posted at the edge of Palen. They had been struck by a large shot, which, towards the termination of its course, had grazed posteriorly both shoulders. In one, Lamey per-

ceived a slight *échymose* over all the back part of the trunk without any apparent rupture of continuity. Respiration hardly went on, and the patient lay a large quantity of frothy venous blood. The pulse was small and intermitting, and the extremities were cold. He died an hour after the accident, as Lamey had prognosticated. This gentleman opened the body in the presence of M. Dubou, inspector of the military hospitals of the army of the eastern Pyrenees. The skin was entire; the arteries, aponeuroses, nerves, and vessels of the shoulders were ruptured and lacerated, the wounds looked in places, the aponeuroses of the corresponding dorsal muscles, and the posterior symmetry of the adjacent ribs, fractured. The spinal marrow had suffered injury; the neighbouring part of the lungs was lacerated, and a considerable extravasation had taken place in each cavity of the chest.

The second instance died of similar symptoms six-quarters of an hour after his arrival in the hospital. On opening the body, the same sort of wound was discovered, as in the preceding instance.

In the German campaign of the French army, Lamey met with several similar cases, and another examination has invariably convinced him of the actual nature of a spherical body, propelled by means of gunpowder.

North case. According to Baron Lamey, when the metallic body has struck before, especially that which has the point of the foot or knee, and the aponeuroses which strengthen these articulations are broken and lacerated by the fire of a ball, or a fragment of other kind of ball, resistance is insupportable. The same resistance would occur, even the ball lodged in the thickness of the external part of a bone, or were it so engaged in the joint as to be about of being extruded by the muscle and osseous matter. (See also *Gallie on Gun-shot Wounds*, p. 137.)

Disasters extending into the pelvis, and accompanied with great laceration of the ligaments, were some of the greatest injuries pointed out by M. Pature as indispensably requiring immediate amputation. (See *Pature on Cancer de l'Uter*, p. 8.) Thus we see the difficulty was not so remote to early amputation as several the late writers have represented.

It is only in this manner that the patient can be rescued from the dreadful pain, the agonizing symptoms, the violent convulsions, the acute fever, the considerable tenderness, and the general inflammation of the limb, which, Lamey observes, are the necessary consequences of late fracture of the large joints. For, adds this author, if the voice of experience is not listened to, and amputation be delayed, the parts become disorganized, and the patient's life is put into imminent peril.

It is evident, says he, that in this case if we would prevent the patient from dying of the subsequent symptoms, amputation should be performed before death, or at most twenty-four hours have elapsed, even M. Pature himself presented this opinion in regard to certain descriptions of injury. (See *de Clin. Medica*, t. 2.)

With respect to wounds of the knee, the statement of Mr. Guthrie nearly coincides with those of Lamey. "I must sincerely grieve," says Mr. G., "I do not remember a case so well, in which I knew the articulation and the femoral vein to be fractured by a ball that passed through the joint, although I have read great numbers, even to the last battle of Tewkesbury. I show that persons wounded in this way live, if only, or a recovery cannot be aided, where the limb is motionless, torn backwards, and a constant source of suffering, to obtain even this partial severity (the impending death), but if one case of recovery should take place in 100, or in any case of resistance to the nature of the wound (the case). Or is the possibility of a limb of this kind an equivalent for the loss of one more?" (See *Guthrie on Gun-shot Wounds*, p. 136.)

In the attack on the village of Morsman, near Antwerp, early in 1834, a soldier of the 5th regiment was brought to our field hospital, having received a musket-ball through the knee-joint. The staff-surgeon on duty, and Mr. Curtis, surgeon of the 1st guards, were preparing to amputate the limb, when a woman attached to the 50th, slightly recommended differing

the operation. Superficial dressings were applied, and the patient went to the tent. He lived several months after the accident, at times exhibiting hopes of a perfect recovery; but in the end, he fell a victim to his injuries.

Indeed, such is the general unfavorable result of these cases, that Dr. Keegan says it does as a law of military surgery, that no wounded man, particularly the knee, ankle, or elbow, should ever leave the field except under where the patient is not seriously injured. — (On Military Surgery, p. 41, of V.)

According to Mr. Guthrie, because of the patient, without injury of the other bones, afraid of delay, provided the bone is not much splintered.

Sixth case. Larrey observes, that if a large laceration, a small comminuted, or a piece of a bone—being, in passing through the substance of a tendon, should have extensively detached the bone without breaking it, amputation is equally indicated, although the soft parts may not appear to have particularly suffered. Indeed, the violent concussion produced by the accident has shaken and disorganized all the parts; the necessary substance is injured, the vessels are lacerated, the nerves (especially) stretched, and motion left a state of stasis; the tendons are injured of their use, and the circulation and sensibility in the limb are destroyed. Before Mr. J. de la Harpe, Baron Larrey remarks upon cases of this kind of disorder. The case can be supposed to happen only in the leg, where the bone is very superficial, and merely covered by its cutaneous part with the skin.

The following are described as the symptoms: the limb is swollen; the foot and wrist, the knee partly exposed, and, or circal examination, it will be found that the integuments, and even the phlegmons, are extensively detached from it. The circulation extends to a considerable distance; the functions of the body are disturbed; and all the motions experience a more or less palpable disturbance. The intellectual faculties are suspended, and the circulation is stopped. The pulse is small and uncountable; the sensibility gone; and the eyes have a dead, vacant appearance. The patient feels such agony, that he cannot long remain in one posture, and declares that his leg may be quickly taken off, as if it incommoded him severely, and sometimes very acute pain in the knee. When all these characteristic symptoms are observed, says Larrey, we should not hesitate to amputate immediately. For otherwise the leg will be attacked with splinters, and the patient certainly perish.

Larrey adduces several interesting cases in support of the preceding observations.

Eighth case. When a large perforated amputation, such as the elbow, or especially the knee, has been extensively opened either during treatment, and blood is extravasated in the joint, Larrey deems immediate amputation necessary. In these cases, the synovial membrane, the ligaments, and synovial capsule, the part vessels, and cartilages rapidly take place; and scale pores, abscesses, discharges, caries, fibrils, symptoms, and death, are the speedy consequences. Larrey has seen numerous instances of such injuries, on account of the operation having been performed through a hope of saving the limb. In the *Memoirs de Chirurgie Militaire*, Ann. 2, some of these are described.

Although a wound may penetrate a joint, yet if it be small, and unattended with extravasation of blood, Mr. Larrey informs us, it will possibly heal, provided too much compression be not employed. This gentleman adheres to the common doctrine of the pernicious effect of the air on the cavity of the body; yet in this place a small wound is alluded to speaking of the free discharge of small vessels of joints, he says, "a joint that is diseased, requires that positive does participate with the common laws of nature?"

When two limbs have been at the same time so injured as to require amputation, we should not be afraid of amputating them both immediately, without any interval. We have seen Larrey, several times performed this double amputation with success as much as upon the amputation of a single member. He has recorded an excellent case in confirmation of this statement. — (*Ann. de Chir. Militaire*, t. 3, p. 67.)

When a limb is differently injured at the same time in two places, and one of the wounds requires ampu-

tion (suppose a wound of the leg with a splintered fracture of the bone, and a wound of the thigh, done with a ball, but without any fracture of the os femoris, or other bony accident), Larrey recommends to be first to dress the simple wound of the thigh and amputate the leg immediately afterwards, if the knee is free from injury. When it is necessary to amputate above this joint, the less important wound need not be dressed till after the operation, provided it can be comprehended in the section of the member, or be so near the place of the incision as to allow the incision. When the wound demanding amputation is the upper one, the operation of course is to be done above it, without paying any regard to the injury situated lower down.

Ninth case. In the foregoing species of gunshot wounds, pointed out by Baron Larrey, as urgently requiring immediate amputation, his own experience and the observations of Dr. Thomson justify me in adding compound fractures of the thigh among gun-shot fractures. I am particularly glad that the latter gentleman has devoted a proper degree of attention to these cases; for the operations which I find of judging when should, and when to believe, that military surgeons hardly yet sufficiently acquainted with the anatomy of these three operations in gun-shot fractures of the thigh. There were brought up to my hospital at Val-de-Aisne, in 1814, about eight of such cases, all in the worst state for an operation, because several days had elapsed after the receipt of the injuries. All these patients died, excepting one, whose fracture was not so above the trochanter, and I do not know, that he ever regained a very useful limb. Another died three hours removed by amputation from the danger of the injury; but was unfortunately lost by secondary hemorrhage about three days after the operation. The bleeding was almost instantly suppressed; yet such was the weakness of the patient, that the irritation of securing the vessel, and the loss of blood together, destroyed it in every stage of recovery. Were I to judge, then, from my own personal observations at the army, and from some other cases which I saw under my eyes, I should without hesitation recommend immediate amputation in all cases of compound fractures of the thigh, caused by gunshot, loaded balls, &c. If there are any exceptions to this advice, they are such as are specified in the article *Amputation*.

Two other fractures of the thigh (says Dr. J. Thomson) have been universally allowed to be attended with a high degree of danger; indeed, all of late years, very few instances have been recorded of recovery from these injuries. Reason acknowledges, that in his long and extensive experience, he had never seen an example of recovery from a gunshot fracture of the thigh; and likewise, in his calculations with regard to those who recovered from gun-shot fractures, he has added these of the thigh bone as being of a nature altogether hopeless. In the present improved state of military surgery, injuries not infrequently occur of recovery from this fracture; but of these the number will be found, I believe, to be exceedingly small in comparison with those who die, particularly when the fracture has had its seat above the middle of the bone, &c.

According to the observations of Percy, scarcely two of them recover of those who have suffered gun-shot fractures of the thigh-bone. Mr. Guthrie, who seems to have paid greater attention to this subject than any preceding author, says, that "upon a review of the truly cases which I have seen, I do not believe that more than one-third recovered to an useful limb; two-thirds of the whole died either with or without suppuration; and the limbs of the remaining third were not only badly mutilated, but a cause of great inconvenience to them for the remainder of their lives." — (*See Guthrie on Gun-shot Wounds*, p. 141.)

In fractures by loaded balls of the lower part of the thigh bone (says Dr. Thomson) recovery not infrequently takes place, and such Thomson and Mr. Guthrie conceive, that they are injuries in which amputation may be delayed with safety. It would be very agreeable, that this opinion should be confirmed by future experience; but it appears to me, that before it can be received as a maxim in military surgery, much more experience and positive observation than we yet possess, will be required with regard to the propriety of those who recover without amputation, or after secondary operations, and of those who escape after primary amputation. Of these who had suffered

this injury, he now comparatively had a small answer referring to Edgemoor, and they had been attended with severe local and constitutional symptoms." (See *Obs. made in the Military Hospitals in Belgium*, p. 487, 488.)

In the article *Amputation* I have described the manner in which this practice restores of several inches of length in the thigh-bone. This state of the bone, observes Dr. Thompson, could be only a consequence to recovery, and his conclusion is, that in general, even in fractures of the lower part of the thigh-bone, a greater degree of force will be necessary in military practice by amputation, than by otherwise, the soft without that operation. "When the bone appears, on a careful examination, to be broken without being much splintered, and when the patient can be removed easily to a place of rest and safety, it may be left to attempt to preserve the limb; but if the bone be much splintered, or if the consequence will be long and distressing, it will be more judicious, I am convinced, to amputate rather than, even in fractures of this part of the thigh-bone, to attempt without delay.

Muscle-balls, in passing through the fragment to the knee-joint, produce lacerations of the vessels, which generally communicate with the joint. These cases, like those in which the ball has passed directly through the joint, require immediate amputation.

The writings of military surgeons contain but few histories of cases in which the thigh-bone had been fractured above its middle by the passage of musket-balls. These are, indeed, few, which have generally had a fatal termination; and the danger attending upon the amputation which they require seems too long to derive different surgeons from attempting to discover what advantage might be derived from the employment of that operation. *Schlesinger* recommends, and states that he has practised with success, amputation in these cases in which a sufficient space would still below the joint for the application of the apparatus. It is curious to remark, in the history of amputation, how long surgeons were in discovering the ease and safety with which the femoral artery may be amputated by the diaphragm, or, as he in the passage over the hip of the pelvis. Nay, from the immediate danger, protracted suffering, and ultimate cure of cases, which he has observed to follow this kind of injury, argues strongly the propriety of immediate amputation. "Mr. *Thompson's* opinion, with regard to the desirability of these injuries, and the advantages to be derived in place from immediate amputation, coincide in every ground with those of *Schlesinger* and *Boy*. He observes, that those whose thigh-bone has been fractured in its upper part by a gunshot-bullet generally die with great suffering, before the end of the sixth or eighth week; and that few even of those escape, in whom that bone has been fractured in its middle part. Of the few whom we saw, who had terrible gunshot fractures in the upper part of the thigh-bone in Belgium, scarcely any are now to be seen in a favorable condition. In all the limbs were much contracted, distorted, and swollen, and sometimes had suppurated within the neighborhood of the fractured extremities of the bones. In some instances, these extremities had passed down the thigh, but more frequently they passed upwards and occupied the region of the hip-joint and pelvis. In several instances, in which recovery had been made for the evacuation of matter, disfractured and extruding extremities of the bones, sometimes contained, and sometimes following the whole of the bone, could be felt hard, rough, and extremely separated from the soft parts which surrounded them. In other instances, these extremities were partially enclosed in deposits of new tissue, which, from the difficulty thrown out, seemed to be produced in a marked degree. It was obvious, that in all of these cases, several months would be required for the recovery of the fractured extremities; that in almost every case pain and misery would be endured from the processes of suppuration, absorption, excretion, and growth of dead bone; that in some cases, the patients were actually great danger from blood-poison, and from the fact that the blood was necessary in order that they were debilitated, and that of those in whom this might take place, there was but little probability that they would be able to do more labor. The worst of these cases (says Dr. Thompson) made a deep impression upon my mind, and has tended to strengthen my con-

clusion that this is, of all others, the state of things in which immediate amputation is truly and properly required." (See this case in the *Military Hospital in Belgium*, p. 484-485.)

Dr. Thompson adds, that when the bone end of the danger of fractures caused by gunshot-balls in the upper part of the femur, is then in a still greater degree of those which have their seat in the neck or head of that bone. In such instances, Dr. Thompson joins the generality of modern army surgeons in strongly recommending amputation at the hip-joint, a notion of which I have already spoken. (See *Amputation*.)

ON SURGICAL WORKS IN WHICH DIFFERENCES MAY BE OBSERVED.

If, says Baron Larrey, it be possible to supply the needs in which amputation ought to be immediately performed, it is impossible to determine, in such cases, which will require the operation with certainty. One gunshot wound, for example, will be cured by ordinary treatment, while another that is at first less severe, will afterwards render amputation indispensable. Whether this be owing to the patient's bad constitution, to the feeble sympathy which are formed. However this may be, the only rule for guiding the surgeon that practice itself is, to amputate immediately in all circumstances in which every resource, as the bone is manifestly in vain. Upon this point Larrey's doctrine differs from that of Pagan.

Thompson's principles are admitted cases, which is some extent of the second kind, in which it allows amputation, not with any hope of curing the limb, but in order to let the first symptoms subside. The system here between the different, and sometimes day appears to have been diagnosed than when performed immediately after the receipt of the injury. At the early period, according to M. *Barre*, the condition continued by the gunshot injury is enlarged, the pain is excessive, based on laceration, the large portion of which the patient has been very severe, as a sign of the danger, the delay of the individual is an objection; and it is laid down as a rule, "in the consequences of every amputation, even in the first instance, are in general extremely dangerous." In support of this theory, M. *Barre* adduces a series of gunshot injuries in which, after the battle of Fontenoy, the operation was delayed, in order that it might otherwise be performed with more success; a plan which, according to the author, proved completely successful. (See *Prix de l'Académie de Chirurgie*, tom. 2, art. 18, item.)

This division of the cases for amputation into two classes, not consistent with justice, Larrey himself has been the cause of a great deal of dispute. Very early the partition of M. *Pagan* large one, and is made in the first instance in amputation. The history is that they are dangerous; while on other occasions they require amputation without any delay.

Larrey, after stating that the effects of amputation, instead of increasing, gradually diminish as it appears after the operation, continues to use together about the possible cause of the ill effects of amputation, which, as being well and satisfactory, I shall not here repeat.

Baron Larrey will not even admit that the patient's state ought to be a reason for postponing amputation, because the patient, just after the accident, will be much less afraid of the risk which he has to encounter, than at the expiration of the first hour and twenty hours, when he has had time to reflect upon the consequences of the injury or of amputation, a point made by the *Business Page*.

Experience agreeing with my theory (says Baron Larrey), however, both to the army and navy surgeons, that the bad symptoms which soon follow each gunshot injury, on their occasion the loss of a limb, are much more to be dreaded than those of immediate amputation. One of a vast number of the wounded who suffered amputation in the course of the first two and twenty hours after the memorable naval battle of the 1st of June, 1794, a very few lost their lives. The fact has been attested by several of our colleagues, and especially by *Perron*, surgeon of the ship *Le Jemais*.

The following is said to be an extract from one of his letters.

"After the naval engagement on the 1st of June, 1794, a great number of amputations were done immediately

after the receipt of the report. Many of the patients whose names had been thus noted were taken to the naval hospital at Marseilles, and put under the care of M. Duret. With the exception of two, who died of sepsis soon after they were moved, and there was one who had long been almost paralysed, the success of the Trepan, which was repeated by the English, was decisive, in compliance with the advice of their medical men, to defer the operation until many of the wounded could be sent off to the naval hospital; but he had the satisfaction to see them all die during the passage." *Am.*

Lafrey next explains us, that when he was sent to the army of Italy, in 1796, he had the pain of seeing in the hospitals great numbers of the wounded, full victims to the confusion which many of the surgeons of that army placed in the principles of M. Pons. General Bonaparte saw that the ambulance service was the only thing that, in the event of fresh battles, could prevent such a misfortune; and at consequence of his orders, Lafrey formed the three divisions of ambulances which are described in his *Mémoires de Chirurgie Militaire*.

Since that period it has always been customary in the French armies, on the day of battle, to make every preparation for performing amputations as speedily as possible. The next night of these ambulances (always attached to the advanced guards), says M. Lafrey, encouraged the soldiers, and inspired them with the greatest courage. On this occasion, the following anecdote is cited from Armande Pons.

"Five hundred warriors having been together sent for by the Duke of Brissac, besieged at Metz, to attend the wounded of his army, who were in great numbers, Armande Pons was chosen to the first advanced battery at the breach. Upon this, they immediately fixed the air with shouts of the most lively joy, and cried out: 'Glorious warriors plus vaillant, ils arrivent plus vite!' Their courage revived, and their confidence in this skilled surgeon contributed to the preservation of a place, before which a formidable army was defeated."

Lafrey desires us to interfere in the middle who have lost one or two of these limbs, and really will tell us that they seldom amputate a few minutes after the accident, or in the first hour-and-a-half hours.

"M. Pons now assigns six positions," says Lafrey, "I presented them to repeat to the first of battle the day after action; they would then soon be convinced, that without the prompt performance of amputation, great numbers of soldiers would inevitably lose their limbs. In Egypt this truth was generally acknowledged."

The following communication upon this point was made in France by M. Mestivier, a French surgeon on duty at Alexandria.

"In the naval hospital of this port I have seen three soldiers or sailors, who were wounded in the great attack off Aboukir, and who had suffered amputation in the first day-and-a-half hours. In two of these the operation had been done on the arm; in two in the thigh, and in three others in the leg. All three men are thriving. In the army hospital there have been only three such amputations, which were performed seven or eight days after the battle, and three patients died a few days after the operation, although the operation was done immediately, and no grave symptoms preceded at the time of the performance. You see, on experience that in this instance you cannot lose principles."

In 1806, during the American war, we are informed by Lafrey, that the surgeons of the French army performed a great number of amputations according to the system then generally adopted in France, that the operation should not be undertaken till after the subsidence of the first symptoms. Almost all the patients thus treated died after the operation. On the contrary, the Americans, who had the business to amputate immediately for in the first twenty-four hours) upon many of their wounded countrymen, lost only a very few. Yet M. Duret, at the time surgeon to the Spanish troops, and from whom Lafrey has collected this fact, relates that the situation of the hospital for the French wounded was, on many occasions, the most disadvantageous. (Lafrey, *Théor. Diagnost. méd. et chir.* 1802, a *Plan de Chirurgie*.)

Admitting that, by a concurrence of fortunate circumstances, which are not always to be obtained, symptoms arising from the change of the first

symptoms, as Lafrey remarks, this proves nothing in favor of doing the operation afterwards; it tends to show what nature just do towards the event of the crisis.

If, at the end of twenty or thirty days, the progress seems bad as it was previously, amputation is to be avoided. Thus all the sufferings which the patient has endured have been undergone for nothing, and the operation will now be attended with considerable risk, inasmuch as the patient may be in a dangerously weakened state.

Whether systems at all, we doubt the efficacy of the operation becomes more probable; but in this case the surgeon, instead of having recourse to amputation, should render his efforts to preserve the limb.

[Dr. Brown, of the U. S. Army, during the late war, described the head of the Veterans after a gun-shot wound received at the battle on Lake Champlain; and soon after, Dr. Henry Hunt, of Washington, D. C., removed the carious and necrotic suppurative of the scalp, the lateral end of the clavicle, together with a superior projecting portion of the os humeri, from the same patient. (See *Am. Med. Recorder* for 1858.)

In this case the limb was preserved by those bold operations; whereas, if amputation even at the time had been attempted, the patient's life might have been the result. — *Am.*]

ON THE REMARKABLE EXISTENCE OF ANEURISM.

Upon this subject Lafrey gives us the asserted formation.

First Case. A spreading Morbification. While disposed to refer to an internal and general cause, it would then be refused as the supposition to accept before either had put limits to the disease. Lafrey declares this kind of progress is better distinguished from that which is termed traumatic, by the symptoms which precede and accompany it. These symptoms are similar to those which are observed in aneurism, such as aneurism. Here the operation ought to be deferred, and endeavours made to combat the general system with regimen and internal medicines.

But when the progress is traumatic, Lafrey advises the limb to be immediately cut off above the disintegrating pain. Several facts in support of this doctrine are related by this experienced surgeon in his *Mémoires de Chirurgie Traumatique*. (See *Am.*)

In this part of the Dictionary will be found additional observations in favor of the practice adopted and recommended by Lafrey, which is in opposition to that advocated by Henry Hunt, and the generality of writers.

In the article *Amputation* I have noticed a particular case of gangrene, which has been noticed by Mr. Gifford, as denouncing the early performance of amputation and a deviation from the old rule of waiting till the circulation has ceased to spread. (See *Doctors on Gun-shot Wounds of the Extremities*, p. 55, &c.)

Second Case. Obstruction of the venous trunk. It is one of Lafrey's doctrines (though of a very questionable description), that amputation of the member, performed immediately after the first symptoms of febrile reaction, themselves, interrupts all communication through the system of the artery and the rest of the body. He states, that the operation immediately venous, and thus puts a stop to the system of the artery and to the circulation of the member. These first efforts, he says, are followed by a general aneurism, which produces the circulation, stops, and the regulation of every part of the system. He argues, that the whole of the traumatic pain caused by the operation must increase the existing aneurism; besides the interference of the venous trunk alone of laceration was bound to, and lower their vitality, especially when the principal vessels of the limb are strongly compressed. Nevertheless will be made as this old rule is the same. *Thibaut*.

Third Case. Bad state of the Discharge. It often happens that in gun-shot wounds complicated with fracture, notwithstanding the most skilful treatment, the discharge issues of a bad quality; the fragments of bone are surrounded with the matter, and have not the best tendency to unite; the patient is attacked with fever, and a colligative discharges. Under these circumstances, the only recourse to be pursued is amputation.

Fourth Case. Bad state of the System. It is probable, as Henry Lafrey observes, the case of aneurism, is sometimes produced as a result of a bad system.

tended by the introduction of an elastic gum catheter, the size of which is to be increased gradually, until the largest can be passed, when the foreign substance will readily enter the ureter, or pass on through the dilated urethra. In this way HENRY LARREY has saved great numbers from a very kind of suffering. (*Ann. de Chir. Mil.* t. 4, p. 302.) In such cases, the urethral syringe made by Mr. WERE might often be used with advantage.—(See *Ephemerid.*) When the ball is too large to be taken out in this manner, the lateral operation is to be performed, and it ought to be done before the bladder falls into an elevated or gangrenous state, from the pressure and irritation of the foreign body. However, as wounds of this organ frequently give rise to dangerous inflammation, Larrey recommends this operation to be done either before or after, to cut off all the consequences.—(*Op. cit.* p. 269.) In fact, almost all the operations of this kind we record have been done some considerable time after the receipt of the wound, and to this practice my own judgment would lead me to give a general preference. In one case, however, LARREY operated on the fourth day after the receipt of the wound, and with success.

After the battle of Waterloo, I was left a little surprised to find, in the *St. Elizabeth Hospital* at Brussels, a considerable number of cases, in which either the ureters, the stomach, the omentum, or the bladder protruded. I think we light in the division under Mr. COLLIER and myself, not long after these operations of the bladder. As before which I referred to just the injury in the field on the 21st of June, deprived me of the opportunity of witnessing the progress and termination of these interesting cases. However, many had ended fatally before my departure from Belgium.

GUN-SHOT WOUNDS OF THE UTERUS.

Wounds of the uterus, distinguished from other gunshot wounds, are now well known and to be always fatal. Balls have been found in the substance of the uterus after having lodged there twenty years, during all which time the patients were healthy, and free from symptoms indicative of the event.—(*Arch. Med.* t. 3, p. 25.) Mr. HENRY had some reason to believe, that wounds of the uterus made with balls were generally less dangerous than such as were made with sharp-pointed instruments; he had seen several patients recover after they had been shot through the uterus, while other persons died of very weak wounds of these organs, done with wounds and bayonets. Perhaps the cause of this fact may be owing to the circumstance of gunshot wounds generally throwing less than other wounds, so that there is not so much danger of blood being effused in the cavity of the chest or the pelvis of the uterus. The introduction of the cavity of a gun-shot wound into the body, is also another circumstance that favours the recovery, as whatever further happens to be distinguished has plentiful opportunity of escaping.

But there what has been stated, it would not be inferred that gun-shot wounds of the uterus are not incompatible with a various degree of danger. Frequently the patient expires instantly, being suffocated in consequence of profuse hemorrhage from these organs; for though it is true that gunshot wounds generally do not bleed much when the injured vessels are under a certain state, yet the contrary is the case when the wounded vessels are like those strained towards the top of the lungs. Gun-shot wounds of the chest also often prove fatal by the inflammation that is excited within this cavity.

Apparatus sometimes create a belief, that a ball has passed, completely through the chest and lungs, when the fact is otherwise. Thus, as Dr. HENRY observed, I have traced a ball, by description, passing into the cavity of the uterus, making the extent of the lungs, penetrating nearly to the point of exit, and giving the appearance of the men having lived and moved about, while bloody spots seemed to prove the fact, and in reality revealed the same, however, is a certain extent, as necessary as it is the case had been what was supposed. The bloody spots, however, were only secondary, and neither so active and alarming as those which were at at once from the lungs when wounded.—(*Medical Repository*, p. 208, et. 2.) A second case of abortion in the frequent long course of a ball, round the chest under the skin and muscles, previously to its exit, whereby an appearance is presented, as if the patient had been shot through the

thorax. And another source of deception, as to the actual penetration of balls, is, "where they strike against a ligamentous, artery, vein, &c., and are driven on, as if they were in their solid, a puncture which has escaped M. LARREY, who gives an interesting notice of it in the *Bulletin de la Faculté de Médecine*, Paris, 1818, No. 5. I have also given an instance in the preceding pages."—(*Ann. cit.* p. 317.) In these cases, the absence of bloody expectoration directly after the injury, the undisturbed state of respiration, and the gross freedom from oppression, anxiety, syncope, and other symptoms, than it comes where the lungs are shot, form grounds for a correct opinion on the true nature of the accident.

It is easy to suppose that adhesions always take place round the opening of a gun-shot wound into the chest, because the lung must necessarily collapse, and become considerably contracted from the pleura, especially when the communication established between the atmosphere, air, and the cavity of the thorax is very free and direct. However, adhesions are extremely common between the outer surface of the lungs, and the outer surface of the pleura viscosa, they would be easily torn away before the receipt of a wound, and, of course, prevent the usual collapse of the lungs.

As the general symptoms and treatment of wounds of the chest are detailed in the article *THORAX*, I shall not here detain the reader long upon themselves. When a patient has light shot in the chest, the most important assistance is to prevent and reduce inflammation of the lungs and pleura. In few other cases is respiration and large breathing to be so advantageously promoted. Here there will not be so much danger of an extravasation of blood as in others, and even if the nature of that shot were to happen within the cavity of the pleura, the opening would generally be sufficient for its escape, and it would not be so frequently necessary to drain the wound or make a new opening, as when the injury has been induced with a sharp-pointed weapon.

In this last kind of case, when attended in the best manner with bleeding, Henry Larrey particularly dwells upon the advantage of immediately bringing the sides of the wound together with adhesive plaster, bound or leaving it open, as directed by the generality of writers, and he recommends to pour, that this immediate measure of the wound has good effect in stopping the hemorrhage from the pulmonary vessels. Proceeding to extravasation of blood in the chest were to follow, it argues that it would be better to let it out and afford it a suitable issue, than to suffer the patient to perish of hemorrhage at once by his coming too much. (*Ann. de Chir. Mil.* t. 4, p. 151, et. 2.) Dr. HENRY is in favour of the same practice.—(*Medical Repository*, p. 272, et. 3.) As a penetrating gun-shot wound of the chest, after taking away from parts so often closed if blood, the surgeon should attend all symptoms of inflammation and effusion of blood within itself, and not direct the external wound like his patients, if he really expects to destroy the disease by this means. The patient may rest in comparative tranquillity, and the spilling of blood, and danger of effusion from internal hemorrhage come to rest, when no direct issue is again employed; and if by this management, repeated as often as circumstances demand, the patient survives the first twelve hours, lungs and lungs is disappointed of his proceeding from those various effects of hemorrhage? and what other danger is there, as Dr. HENRY truly observes, as he knows it to be only those which can cure him. Afterward, when the paroxysms of pain, the sense of suffocation, and the nature of hemorrhage have become more considerable may be prevented with the most successful result, but if the cough be very troublesome, or some case is more fatal than the symptoms suggest with squam. With this treatment kept so constant the exhibition of saline purgatives, expectorative syrups, and a strictly low diet, the patient being allowed no sleep.—(*See Medical Repository*, p. 272, et. 3.)

When water enters the thorax, it is considered gun-shot wounds, the opening will generally follow in its escape; but should the collection of air be confined, and because dangerous symptoms, the chest would soon either be enlarged, or a new incision produced, as circumstances may require. The work of making an opening into the chest is considered in the *Article Pneumothorax*.

When a ball lodged without falling into the river, it may be either in the stomach or in the bowels of the patient between the epiglottis, or it may be in the intermediate space, and sometimes above a very long time without causing much inconvenience or leading to any serious results. But when it is ejected at the throat or cavity itself, it depends on the weight and compressing capacity of the foreign body. In some cases, it causes considerable difficulty in deglutition, extreme and constant oppression; in others, if the stomach can be accommodated, there being temporary distention, it causes no result. In an early stage of the disease, it says that the inverted stomach will often be weak enough to let the ball pass slowly; it, but that, at a later period, that same stomach has become, and it will be necessary to cut away a portion of the upper edge of the rib with a bistoury, after which it will be preferred to a tracheotomy now. This advice is supported by some very interesting cases. (See *Annals of Chir. Med.* &c., p. 282.) Frequently the ball fractures the rib and, with the aid of dilators, sufficient room for its extrusion may be made; but the possibility and security of operation, if through the surgical opening, will, of course, depend upon the situation of the foreign body, and the urgency of the symptoms. A case is recorded in which a ball, weighing seven ounces and a half, was thus removed.—*Med. and Surg. Jour.*, vol. 3, p. 300.

GUPTA SIRENA A fern seed to have been first sown by Actinaria to amuse him, or the species of him, from arising from a world state of the resin or optic nerve. (See *Amusements*.)

In the present place I mean first briefly to advert to a case which the late Mr. Ware has described as conducted with a particular kind of propriety, that occasionally excruciating pain, and several peculiar troubles. One example of this kind was gently relieved by a structure made through the nostril, introduced into the ball of the eye with a grooved handle, somewhat larger than a common-sized smoking pipe, twenty in the past where this instrument is introduced in the position of depressing the cornea. Through the lower of the instrument, a wad of lint is immediately sent, which was not unlike that which Mr. Ware would give. Some of the death ensued between the second cure and still in cases of still some. After the pain of the operation had ceased, the patient became easy, and the inflammation soon subsided. Mr. Ware afterwards performed a similar operation in a remarkable number of scabulous ulcers, and in several of these the proceeding was attended with almost instantaneous good effects.—(See Ware on the Operation of Faradizing the Cornea of the Eye, in the *Journal of Medicine*, &c. and in the *British Review*, incorporated into *Pain and Insensibility*, &c. &c.)

Enter the head of state, which I assumed to receive her's various nonverbal, automatic reactions, which I divided into two classes, viz. general or internal ones, and local or external. Sometimes only the first is psychic; the second, rarely, only the second; but frequently both together.

making the *Chlamydomonas* fast growing, which may mean it is free from a virus or real contaminants, as an existing disease. It was Roy's opinion that for the purpose of making actual vaccines they should be infected only when the monkey is dead, and not vaccinated by these means; and he drew these appropriate manner by goat vaccination of blood to the head and eyes prevails, or any increased virulence of the system. Should the viruses find it necessary to employ specific treatment, simply an alternative, he must consider too whether the vaccine viruses will have any gross and long continued operation. (Latter part of January, 1922, p. 103.)

Notwithstanding the favorable accounts given by Schneider, Huber, and others of the good effects of vaccines in many cases of infectious disease, the treatment has had but little success in England. Mr. Travers says elsewhere that there has resulted an outbreak of clinical human measles in London, although he has fully tried it. "The use of passive disease, in which it is generally made.

should thus be relieved without with antiseptic treatment, which is especially indicated where there is reason to believe that the granules have been produced, and partly produced, by a long interruption of the catarrhal secretion.

First says, that symptomatic means are attended with the most blunted good effects in that stuporous weakness of sight which sometimes occurs towards the end of pregnancy, and is combined with obstinate constipation, cerebral headache, violent determination of blood to the head and eyes, and such an extraordinary dilated membrane to explain. On the other hand, the employment of counter-stimulant remedies, as leeching, is, in precisely useful in hyperæsthetic and hysterical catarrhal conjunctivæ, when they are treated with much general energy and vigour of the treatment—(Vol. vi. p. 673.)

According to the statements of the same writer, heat, whether warm or cold, adapted for the whole body or to the form of a compress, a friction or affusion, have likewise not proved very efficacious remedies for strabismus; and that, whether they consist of simple water, or aromatic decoctions, or of waters impregnated with sulphur or iron. The means only tried in general are less frequently employed, as empirical remedies in cases of strabismus, and why they are still more rarely successful, may be because in the very cases of strabismus in which both of various kinds are clearly indicated the greatest attention must be paid to the patient's constitution, to the state of the vital system, and to the disposition of the fluid employed; for, as a healthy subject, too warm a bath, even under strabismic circumstances (as the fulgure, when there is phlogosis), or too strong a current, may produce strabismus; and therefore, under similar circumstances, it may be likely to increase any pre-existing strabismic tendency or might into complete blindness. In general, baths of sulphur-baths may be employed as empirical remedies in strabismus only when the regular action of the skin is disturbed, without other symptoms, when the affection of the eye is not hindered by the rapid escape of a profuse perspiration, or some catarrhal effusion is combined with the strabismus. On the contrary, perfusions with salt, nitrated, Ac. are equally proper when strabismus is accompanied with a determination of blood to the head and eyes, or any local inflammation, after which the eyesight is always found to be more. In cases of strabismus, affusion can be useful even empirically, and only under those circumstances where modern experience has proved the shower-bath to be efficacious. Cold bathing generally agrees best with an anæmic patient, and when his skin is extremely sensitive, when washing pains are felt between the superciliary and nostrils, or there is a tendency to erysipelas inflammation, the power of cold, evidently declines after every trial of the plan. But, according to Boer, mineral waters impregnated with iron in the form either of a bath, or use full or for the whole of the body, generally produce, under these circumstances, the most favourable effects upon the skin, and through the medium of it, upon the diseased eye. The case, however, also is accepted where flying rashes, and perhaps pox, pass over the face; the patient, under such a plan, and when bathing of the whole body in sulphurous mineral water should be pursued—(Lect. res. des. Journ. 2, p. 471, 472.)

If we are to believe Boer, the empirical employment of applications which have the effect of increasing the secretion of humors is very seldom proper, such as irritating farinas, the smoking of saltpetre, and mustard, &c. neither does cold only be adapted with any prospect of benefit, when strabismus is accompanied with phlogosis, a series of spots and would avoid the frontal sinuses, an abundant, often profuse at the sides of the nose, and lateral crysals of the nose, in an individual who has frequently suffered catarrhal conjunctivæ, but some have previously to the origin of the strabismic symptoms had suffered nearly or quite free from such; and when the patient has no tendency to phlogosis, determination of blood to the head and eyes, and tenderness of the strabismus—(Vol. vi. p. 473.)

The application of counter-stimulant remedies to the nose, in perhaps, to be regarded as a mode of treatment established on empirical principles, when we can place confidence in the statements of A. Leake, Richter, and Boer, that an increased crysals of the nasal membrane

of the nose, following fatigue and wear in strabismus, may have the effect of inducing anæsthesia. The case is played by Richter's following compound: R. Mucos. vir. 3i. Sacchar. alb. 3ss. Inf. alb. and rectify a 274 Mf.

The late Mr. Ware required considerable efficacy to destroy and a secretarial staff in cases of gummy eye. The word was composition of the grains of yellowish phlogistic sulphureous, well mixed with about a drachm of the purest succinate, glycerine, or common wax. A small piece of this stuff taken up the nose, as found in strabismus it was immediately; sometimes exciting swelling, but in general producing a very large discharge of mucus—(See Lib. the. vol. 2, p. 474, 475.)

Among the remedies which are intended to be applied directly to the eye and its surrounding parts, local bleeding, made by the fistula, is the extraction of blood by means of leeches, or by cupping the temple, is the only mode in which the matter can here be executed. This method, however, is only proper when violent influences of the result of the congestion and inflammation is combined with a feeling of constant pressure about the eye, a sense of fullness and tension in the ball, and violent pulsations, without any local inflammation or increase in the velocity of the circulation.

Appropriate phlogosis also, says Boer, that the empirical application of tubercles, or drying plaster, to the temples or eyebrows is thought well, but less efficacy when all sensibility in the retina appears to be extinguished, when any action in the vessels of the eye, and various characters of the blood-vessels, or any peculiar determination of blood to it. Appropriate phlogosis or determination of blood, including both internal and external anæsthesia, may be advantageously employed upon the eyelids and temples, when there are grounds for believing that the functions of the skin have already been long suspended by phlogosis, or the absorption of perspiration on the forehead—(Boer, Lect. res. des. Journ. 2, p. 474.)

As in the various plan of treatment, the rubbing of fluid, pungent or irritating substances upon the eyebrows, in certain kinds of anæsthetic blindness, is often attended with considerable efficacy; so, in Boer's opinion, it should not be neglected in cases where the subject is susceptible to have recourse to stuporous methods of cure; for instance, when it is observable that generally in the evening, or the night, the eyesight is more or less restored; that in the patient's first waking in the morning, it is weaker than in the middle of the day; and what particularly recommends, while the case is attended with any sensation of imaginary flames of light; a very light or merely shaded vision of the iris; or the least vestige of any defect in the structure of the eye; and no symptoms of determination of blood to the head and eyes, or of a general tendency to inflammation. Boer recommends pungent applications to be first tried, such as the spiritus aromaticus, or tincture of opium. These may be followed by appropriate anæsthetics, as the spiritus aromaticus, like the tincture of opium; and finally, by irritating remedies, like the tincture of iodo. The nature of iodine I should also consider an application well-deserving of trial. These applications which are applied in the form of vapor to the eye demand greater circumspection, like naphtha, the liquor arsenicus, &c. These may be best applied, by putting a small quantity of them into the hand, over which the eye is to be held in such a manner that some of the fluid will come into contact with it. That as soon as the eye begins to be irritated by the vapor, the hand to rise, or actual pain to feel, the hand is to be removed, but too much irritation be produced—(Boer, vol. 2, p. 475.)

Not only in the rubbing, but also in every scientific mode of treating anæsthetic eyes this author, with commendation, is intended to produce a shock upon the nerves and vessels, require the utmost caution. Because, of all the various causes of anæsthesia, they are the most powerful; and consequently, if a shock, any likely to produce an anæsthetic weakness of sight, or complete blindness. This anæsthetic event is most rapidly produced when applications of the description are employed in patients subjects affected with partial determination of blood and local inflammation, a various state of the blood-vessels of the eye, defects in the transparent parts of the organ, or frequent anæsthesia. To the class of remedies being especially the

The next example reported by Port and Richter as a form of haemorrhoids, is not admitted by Richardson, *Journal (New York) des Sciences Méd.* 1. 50, p. 120, and other modern surgeons.

"It," says Mr. Port, "should be extravasated within the uterus, vagina, or proper out of the os uteri; it constitutes a great relaxing and (as it were) extension of part of the vascular compass of that gland, and the quantity is considerable. It will afford to produce a distention in the hand of an examiner very like to that of a lymphoid or tumorous growth; allowing extension for the different density of the different fluids, and the greater depth of the former than the latter."

If this is nothing for a vesigo-haemorrhoid, and an opening to exist, the discharge will be blood; not fluid or very thin; not like to blood circulating through the proper vessels; not dark and dirty in colour, and mostly of the consistency of thin clots (like to what is most frequently found in the vaginae vaginalis). The quantity discharged will be much smaller than when passing from the size of the vessel, which was not so considerably diminished. When this small quantity of blood has been so derived off the vessels will, upon examination, be found to be much larger than it ought to be, as well as much more dense and dirty. Instead of this tenderness and resistance arising from a healthy state of the gland, within its firm strong coat, it is soft, and capable of being compressed almost flat, and that generally without any of the sharp and lancinating which always attend the compression of a sound testicle. If the bleeding occurs upon the withdrawing the os uteri, surprising a froth to have been found with the peritoneal folds, a fresh accumulation of the same sort of fluid is soon made, but the same degree of tenderness is produced as before the operation; if the os uteri does not close, the haemorrhage continues, and very soon becomes alarming."

"In the first two species, the blood comes from the uterus vaginalis, the vessels itself being cut and extravasated, and the tendency is toward the cavity of the testis there; but in this the haemorrhage comes from the substance of the testis, from the vascular fluid of the spermatic artery within the tunica albuginea; the direction of the vaginal coat can have no good; and an unusual trade into the spermatic can only increase the mischief; the testicle is applied, or removed passive, by this kind of attention made to it previous to the extravasation; and insertion is the only cure which a patient in such circumstances can deliver upon."

I confess that no good reason appears for arranging cases of the preceding kind with haemorrhoids, for what else they but diseased testicles which have been penetrated, either on account of their tendency to rupture, or early having within them some other fluid with a morbid colour or other fluid, as I have seen in boys, drops of testicles, of spermatic, and whenever blood is extravasated is not extravasated in the substance of the testis, but in the peritoneum, but seems to be a necessary consequence of that proceeding; however, at the propriety of the practice advised by Mr. Port, no doubt can be entertained.

The last species of this disease noticed by Mr. Port seems from a bursting of a branch of the spermatic vein, between the gland and scrotum, in what is commonly known by the name of the spermatic plexus. This, which is generally produced by gross or sudden exertions of strength, leads of injury, &c., they happen to persons in the last hours, whose blood and gases are in morbid order, and whose genital parts are free from blood or disease.

The effusion or extravasation is made into the cellular membrane, which invests and surrounds the spermatic vessels, and has sometimes the appearance of a true liver. When the case is clear, and the extravasated blood does not give way to decomposition, the only remedy is to tie the spermatic duct upon the whole length. If the vessel or vessels be small, the haemorrhage may be restrained by mere compression with dry lint, or by the use of styptic; if it be large, and these means do not succeed, the ligature must be made use of."

I cannot conceive, Port in ignorance of a third report of one of the spermatic veins, it was ever to be put aside while the whole spermatic duct, and this is better confirmed, though Mr. Port advises this plan. In case the

bleeding length cannot be tied singly. Diseases of the plexus, and an unusual plexus, still almost always depend the swelling, and if not, opening it, taking out the blood, applying cold, or, if necessary, tying the cavity with lint, and using compression, would be, according to my humble judgment, the most judicious treatment.

A consequence of the latter kind is not very common, yet Mr. Port has not created it as one of his forms of haemorrhoids; but why he has not taken notice of the most frequent of all the varieties of the disease, I am at a loss to comprehend; I mean the extravasation of blood in the loose cellular membrane of the scrotum from injury on the part, and sometimes from intemperance, castration, &c., quite unconnected with any rupture of the spermatic veins. "These are the cases which are mostly met with in practice. I have seen them followed by suppuration; but in general the effused blood is gradually absorbed, with the aid of external applications, leeches, incisions, potasses, and saline purges. A surgeon should generally be reluctant to lay open the scrotum, as it is thus situated, absorbing and very severe symptoms have been the result."

Cases and Patients. *Scrotum* are the best of the old writers on haemorrhoids. For modern information, consult Pott's *Cases*, Warton's 2. B. 2d, *De Haemorrhoidibus*, Pott's, *Tractatus de Haemorrhoidibus*, 2. Richter, *Anfangsgr. der Heilkunde*, 2. B. Richter, *Neurologische Clinic*, 2. B. *Chirurgie*, in *Neurologische Klinik*, 2. Moderne*, vol. 5.

HARE-LIP. (*Labiæ Lepræ*.) A fissure or permanent division of one or both lips. The term has arisen from the fissured appearance of the part to the upper part of a lip. Ordinarily the fissure is more or less oblique. In general, it is directly before the apex of the nose; but sometimes it corresponds to one of the nostrils. The two portions of the lip are generally movable, and not adherent to the secondary process; in some instances, given they are closely attached to the bone part of the jaw.

Children are frequently born with this kind of malformation, which is called a natural hare-lip, while that which is produced by a wound is called acquired. Sometimes the portions of the lip, which ought to be united, take a considerable distance between them; while in other instances they are not much apart. The cleft is occasionally double, a little hole or small portion of the lip being situated between the two fissures.

The fissure constantly affects only the lip itself, and usually the upper one. In many cases, however, it extends along the bones and soft parts forming the palate, even so far as the trachea; and sometimes those bones are greatly wasting. In a few instances, the jaw not only is imperfectly ossified in front, so that a cleft passes through them, but one side of it projects forward, and is at the same time inclined too much outwards, drawing with it the corresponding part of the palate, and the septum nasi, so that a very strongly distortion of the postulated nose is produced. The nose, I believe, has not been described in surgical books.

A hare-lip, in its least degree, occasions considerable deformity; and when more advanced, it frequently hinders infants from sucking, and makes it indispensable to sustain them by other means. When the lower lip alone is affected, it is always seen as a malformation, the child was either retained natural, or born to speak, except with the greatest impediments. The constant escape of the saliva, besides being an annoyance, is found to be detrimental to the health; for its loss impairs the digestive functions, the natural mucus secreted, and even death would sometimes ensue, if the frequent discharge of so necessary a fluid in the nasal cavity were not prevented. Thus, a lady, who was in this state, consulted Tronchin, who immediately saw the cause of her indisposition, and recommended the fissure in the lip to be secured; the operation was done, and the dyspeptic symptoms then ceased. And when this disease penetrates the palate, the patient not only suffers very grievously, but cannot swallow, nor swallow, except with great difficulty, on account of the food easily going up into the nose.

An early removal of the deformity must obviously be

very desirable, but, as it cannot be accomplished without an operation attended with some degree of pain, Dumas, Chevreton, and others advise waiting till the child is four or five years old, on the supposition that, at an earlier age, the child's agitation and cries would render the operation impracticable, or damage all the proceedings taken to ensure its success. It is plain, however, that such reasons are not of great weight. A child, near to five years old, and very often even one eight or ten years of age, is some difficult to manage than an infant only a few months old. Every child of the above age has, I thousands have more dread of the pain, than of the deformity or of the inconveniences of the complaint, to which he is subjected; while, in fact, of tender years bears nothing and only feel the pain of the moment.

A more rational objection is the liability of infants to convulsions after operations, and this has indeed nearly occasioned me to postpone the cure of the hare-lip till the child is about two years old. This opinion is now sustained by Sir Astley Cooper, who mentions in his lectures several instances, which, like other leeches communicated to him by others, or have occurred in his own practice, where operations for the cure of hare-lips in very young infants have had a fatal termination, in consequence of an attack of convulsions or diarrhoea. The period when duration is completed, at the age of two years, he therefore recommends as the age of advantage for the operation, and if parents ever so being done earlier, he very properly advises the attempt to let them be fully apprised of the risk, at this is the event of the child being cut off, he may not term him for having operated at an unduly early period of life.—(See LANCET, vol. 3, p. 108.) The latter end of 1832, I met Sir Astley Cooper in consultation in a case where this objection occurred. The deformity was particularly knotty, in consequence of the upper jaw-bone being imperfectly united to itself, and the side of it forming a considerable protuberance forwards through the lip, which extended up to the nostril, at the same time that the nose was seriously distorted to one side of the face. The parents, persons of the first respectability, were therefore unanimously advised as for surgery operations, were instances of the success of which in very young infants had already been communicated to them by their friends. The projection of bone, they had now learned, might be cut away, so as to permit the soft parts to meet, which they now would not do. The risk of an operation on the infant in question, then scarcely two months old, was fairly explained to the parents, but I doubt whether they could have been prevailed upon to wait three months longer, had not Sir Astley Cooper recommended to them the disadvantages of waiting away the best period, and urged the advantage of a little time to ridage the protuberance by means of pressure. As I had not had any previous conference with Sir Astley on the subject, I was particularly gratified in finding his advice agree precisely with what I had already given, when the case was first shown to me. Exactly when the infant was five months old, a period selected as beyond all the danger the infant previously to the total time of the cure, notwithstanding the absence of dentition, I performed the operation in the presence of Messrs. Jern, of Chertsey, and Mr. Ives, jun., of Chobham. By this time the nose had been so effectively depressed, by means of a kind of splint, constructed by Messrs. Searles and Ives for the purpose, and worn several hours daily, that the soft parts situated of better brought into it with tolerable facility. Union followed very well, and, though it was open to the worst hare-lips ever seen by Mr. Ives, senior, or myself, without an extensive division of the lip, the improvement is now very great, and the strong depression of the nose constantly obliging further depression, in proportion as the jaw recedes whilst the pressure of the apparatus, which is still retained.

This is the youngest infant on which I have operated, but, in October, 1831, I performed the operation on a infant twelve months old, at White's Tavern, where I was kindly assisted by Mr. Birdwell, surgeon in that town. Union took place very favourably, without any inflammation whatever. Only one jet was used at the lower part of the lip, as I found that the upper part of the division could be perfectly and readily closed with a strip of adhesive plaster.

Mr. Searles observes, "through every lip where the

loss of substance is so great, that the edges of the tissue cannot be brought together, or at least when they do but just touch, in which case it would not be without its peculiar advantages. It is likewise useful in young children, and with reason, if they suck; but otherwise it may be associated with great safety, and even with more probability of success than in infants that are older."—(Lectures on Surgery, chap. 24.)

Dr. Ross conceived the operation on children at an age even as those in the breast. He held out a great success on infants only three months old. With respect to it to be undepended on soon as the child is six months old. Rossington operated on Thomas, a female after birth, and all the consequences followed her singular debility and nervous. An essential step to the success of the operation, is the management of the children from infancy, a judicious length of time before it was undertaken, a story that they might fall asleep immediately afterwards, and with the same view others have been modified.

Putting out of consideration the parents' interest, which has attended the use of blistering plaster for raising the edges of the fissure raw and capable of union, all practitioners externally the same treatment with regard to the aspect of the operation, which consists in raising the protruded portion of cartilage to the side of a single wound, by cutting off the edges of the separated parts through their lips, and then bringing those parts in contact until they have mutually grown together. But although such practice has been generally admitted, there have recently been differences of opinion with respect to the best method to be followed in practice; some operators having preferred sutures for keeping the edges of the wound in contact; while others disapproved of this, saying that a perfect cure might always be accomplished by means of adhesive plaster and a strong bandage, it is to give the patient from all the pain and uneasiness of surgery.

Mr. Evans thought that the use of sutures in the operation for the hare-lip, proceeded from a false idea respecting the nature of the disease; for the fissure in the lip being well adapted to loss of substance, it was deemed expedient to keep the parts in contact, except by a suture.

"The separation of the edges of the fissure in the lip," says Mr. Lucas, "is only the effect of the traction of the muscles, and is always proportioned to the extent of the cleft. Persons with hare-lips are capable of bringing the sides of the fissure together by muscular action, by puckering up their mouths. On the other hand, the separation is considerably increased when they laugh, and the breath appears constantly large after superficially paring off the edges of such cases. The extension in the hare-lip need not, therefore, be confined to a loss of substance. This truth is confirmed by the effects of strapping plaster, which has sometimes been applied to the hare-lip, as a temporary measure before the operation, and which usually increases the separation of the parts.

According to the contents of all who have written in favour of the rectified suture, it seems to me only as the false idea, that the hare-lip is the effect of a power of less loss of substance; and they say, positively, that we must not have recourse to it when there is only a simple division to be united. The rectified suture must then be preceded from the operation by the natural hare-lip, since it is proved that the rectification is attended with loss of substance. At the same time, a loss of substance is far too real, and the extension of cartilage and substance fissure, in which the lips are very united. Yet, even in some cases, the extensibility of the lip allows an attempt to be made to remove the fissure by means of the former has been entered, and it is enough to find the result satisfactory, when care is taken to direct such incision obliquely, so that both of them form, when they meet, a sharp angle, is the base of which the fissure is extended. Here the means of union might be the best effect, because the difficulty of keeping the edges of the wound apposed is greater. Mr. Martin, in his memoir on the strapping plaster, when speaking of the hare-lip has strongly expressed, that they are badly-considered means, and more harmful in proportion as there is a greater loss of substance, because the greater the interference is between the two parts, the more fear is there of their effects on the

needles or pins left in the wound. Hence, care has always been taken to make the drawings and the operation of the suture. After this consideration, judiciously made by the persons of this plan, there was only one thing left to be done, according to M. Pilon, in order to ensure the success of the operation. The use of copper bandages described by Yrizar and Naub, for compressing the cheeks; the change of linen; and strips of adhesive plaster; are all daily necessities for the support of the plan, and keeping them down being neglected. When the suture failed, it was by these means that the original defects were removed, together with that produced by the laceration, which would not have occurred without the suture. As then, the drawings, when judiciously applied, are capable of effectively removing the mischief of the suture, M. Louis ignores, why should they be considered only as a resource in a mere accidental case? Why should they not be made the chief and primary means of restoring the lip, even when there is a loss of substance?

Nothing can be opposed to the plan, added any thing more. They are well drawn from the pencil of those who have employed suture without success. Such persons have themselves furnished the proofs of the bandages being capable of improving the treatment made from the treated suture.

M. Louis, with a view of perfecting our notions on this matter, has it down as a first, that the retention of the suture being the cause of the separation of the edges of the fissure, it is not to these edges we are to apply the force which is to draw them; but that it should be applied chiefly to the very parts, where action (the cause of the separation) is to be opposed, and where contraction is thus to be prevented. A great many notions for supporting the wound, only divide dissensions and cause them to arise, and this thousand which we should endeavour to overcome. The means of preventing action can only be intellectual, when directly employed to prevent action, again afterwards application in the point where it is to be resisted. The facility with which the parts may be brought forwards, so as to bring the two commissures of the lip into contact by the mere pressure of the hands, shows what may be expected from a very simple apparatus, which will excite the same effect without any effort, is a firm and permanent master, and which will render suture unnecessary, the inconvenience of which are well known.

M. Louis, after having explained the reasons of the theory on which he founded his method, relates several cases, taken either from his own practice or that of others to illustrate the advantages. He details the history of twenty cases in which his plan perfectly succeeded, both in accidental lacerations, with considerable loss of substance, and in natural ones. In most of these instances, however, it was thought proper to secure the bandage with one stitch at the extremity of the fissure, close to the vermilion border of the lip, for the purpose of keeping the parts securely on a line.

Notwithstanding the operation as performed with the treated suture is opposed, by an authority of such weight as that of M. Louis, still it is the method most commonly practiced. No modern surgeons doubt that a lip may be cured by means of adhesive plaster and making bandages, as perfectly as with a suture; and all ready agree, that the first of these methods, as being more simple and less painful, should be preferred to the latter one, if it were equally sure of succeeding. But it is contended for more certainty in its effect. To accomplish a complete cure, the parts to be united must be maintained in perfect contact, and they have required the necessary attention; and how can we always depend upon a bandage for keeping them from being displaced? What other means, besides a suture, affords in this respect perfect security?

I shall first describe the operation as usually done by surgeons of the present day with the treated suture. The first thing is to enquire whether there is any adhesion of the lip to the gum; and if there be, to divide it with a knife. Some authors (Sharp) recommend the fracture, which attaches closely to the gum, always to be divided; but when the lip is at some distance from this part, it will not be in the way of the operation, and need not be cut. On the other hand, when the fracture is situated in the course of the fissure, it is clear that it operating, we must necessarily divide it in the incision, and if should therefore

be divided beforehand, taking care not to encroach too much upon the gum, but the bloody process be laid bare; nor too much upon the lip, because making it thinned would be disadvantageous to its union.

When one of the lower teeth opposes the fissure, jaws forwards, it must be drawn out, and removed and irritate the parts after they have been brought into contact.

Sometimes, but particularly in cases in which there is a cleft in the lower part of the palate, a portion of the or maxillary superior forces such a projection, and in the situation of the fissure in the lip, that it would render the union very difficult, if not impossible. In this case, however, the common plan has been to cut off the projecting angles of bone with a strong pair of bone-nippers. The part was then healed, and the operation for the hare-lip performed. Instead of cutting off the projection of bone, which is always a painful measure, I have tried to employ simple compression, by which means the projection was usually reduced in a few weeks, and the opportunity afforded of operating for the cure of the fissure in the lip (see Clin. par. Rollat, t. 2, p. 307). Of course, the actual necessity of using bone-nippers, or even of having recourse to compression of the bony projection, will depend upon circumstances; for if the prominence of bone be sharp and angular, no surgeon, I conceive, would hesitate about the removal of such irregularities of the surface to the end of cure. Mr. Davis, of Edinburgh, has expressed to me his doubts whether cutting off the prominence of the alveolar process be ever necessary, in the treatment of the cleft lip gradually dissolving, the deformity. "I had thought two very eminently cases, without taking any division of the palate, together with a projection of the alveolar process, which, with the incision made, resembled the lip of a hare." A subsequent appearance of this very typical lip, bone of the nose. In drawing the teeth in the first case very delicately, I avoided fracturing the bony process. Then cut off one edge of the bony appearance, and of the lip on the same side, and attached them together with two threads. The wound was judiciously treated in a week or ten days to allow the second operation on the other side. In one of the three weeks the boy was sent home quite well. In the attendance of the neighbourhood, where his beautiful appearance had made him an object of disgust and ridicule. I succeeded in the other case even without the extraction of the teeth. Both the patients can now articulate like other people, retain their nativity, and are probably losing the inconvenience of the passage of the saliva from the nose into the mouth, as the fissure is more contracted, and the projection by no means so disagreeable." These cases should induce the hands with which certain operations succeed in cutting away projection of the alveolar process; for a moderate protrusion of bone without any sharp, irritating edges or angles, will not hinder the success of the operation; and even the property of removing teeth may entirely depend upon their being truly, by their direction, to irritate the lip, and destroy the union of the fissure.

One serious objection to trying the projection of the part is the deformity afterwards likely to continue during the time the deformity of the alveolar teeth; and another is, the subsequent overlapping of the lower jaw, and its projection beyond the upper one; corresponding to the mouth an appearance seen in very old subjects. These were the considerations which induced me, in the case above mentioned, to employ pressure, which is much more judiciously applied by means of a kind of spring-band, adapted to the shape of the lip, and with bandages, which would be seriously prejudicial, and the right action of which could not be resisted without the utmost difficulty. When the bone of the lower jaw be cut away, an attempt at its readjustment and angular position, I advise the practitioner to remove only the irritating parts, and afterward leave nature to possess.

In the operation, the great object is to make the mouth and even a cut as possible, in order that it may more readily unite by the lips intention, and of such a shape that the nostrils may form only one narrow slit. The edges of the fissure should, therefore, never be cut off with scissors, which constantly divide the tissue which they divide, and a sharp knife is always to be preferred. The best plan is, either to place any dis-instrument, such as a piece of horn, wood, or

nearest commissure, a rounded red substance is necessarily situated, which is so absolutely necessary to its life in the suture. Were this neglected, the tissue below would be exposed, and, through an impudic economy, a degree of deformity would result. The great error, however, is to make the two incisions diverge at an acute angle, so that the edges may be put into reciprocal contact their whole length, without the least difficulty.

M. Lonsie used to operate as follows:—the patient being seated in a good chair, his head is to be supported on an assistant's hand, who with the fingers of both hands presses the cheeks forward, in order to bring the edges of the fissure near to each other. These are to be tied on a piece of parchment, which is to be put between the jaw and lip, and be as thick and a half long, then twice to three lines broad, and not more than line thick. The upper lip should be stretched by fastening the surgical handle to facilitate the incision, the lip is to be stretched over the parchment, the operator, holding one person over the right with the thumb and index finger of the left hand, while the assistant does the same thing on the left side. Thence being thus disposed, the edges of the fissure are to be cut off with two strokes of the bistoury, in two oblique lines, forming an acute angle under the fissure.

For the removal of the edges of the hare-lip, surgeons have variously been prevailed to a knife; but notwithstanding Dondett's jealousy so there, as most convenient (see *Quart. Rev. Med. & Surg.* 1796, p. 176), they are now very generally discarded. The paring and breaking which result from the action of the two blades are circumstances which cannot be favourable to the union of the wound; and though they are not necessarily to be recommended to prevent union by the first intention, they are so commonly tried, with dry after treatment, or under the influence of error. Let our practitioners have been led by Mr. B. Deffenham, that he was terrified by cut of one side of the fissure with a knife, and the other with scissors; that the latter cut produced no pain, and that on this side there was no more exciting inflammation than on the opposite ear.

The pins should be introduced at least two or three of the way through the substance of the lip, four or five should make up the rest of the part, which might prove troublesome by drawing pieces of food so long as it. There is, however, a stronger reason for attending to this circumstance, viz. the hemorrhage which may take place when it is neglected. As soon as the edges of the wound have been brought together by means of the suture, and the pins are properly placed, the bleeding almost always ceases; but when the pins have not been introduced deeply enough, and the posterior surfaces of the incisions are not applied to each other, the blood may continue to run past the mouth, and give the surgeon an immense deal of trouble. In the present method by Lonsie there is a case in which the patient died in consequence of such an accident. Persons who had undergone the operation were always advised to swallow their spittle, even though mixed with blood, in order to avoid disturbing the wound by getting rid of its effluvia. In the case alluded to, the patient, who had been operated upon for a sanguine affection of the lip, swallowed the blood as he had been directed to do, and he died so profusely that he died. On the examination of the body, the stomach and small intestines were found full of blood. "This desperate case," says the illustrious author who relates it, "deserves to be recorded for public instruction, for the purpose of keeping alive the attention of surgeons on all sanguine affections, as consequences of any operation whatever, there is no means so apparent bleeding in the cavity of the mouth. Further is the worthy writer tells, as he and I have, become thick and of danger. The bleeding from the edges of the wound stops of their days but as soon as they have been brought into contact and stretched together by our care, we must be taken that the vessel does not swallow the blood, which would make him vomit, or even swallow him. Hence, his head should be elevated that the blood may escape externally, a pretension more particularly necessary in young children."

Having described the mode of operation by the hare-lip as approved of by the majority of practitioners, and retained every thing which seemed unusual, I have now only to explain the method accepted by M. Lonsie. His

sentiments respecting several particular points of the operation have been already stated; and an account of the means which he employed in lieu of the twisted suture, for making the edges of the wound, is all that remains to be noticed.

Several bandages for supporting the raw portions of the divided lip, and keeping the pinholes which they make against the pins, have been mentioned by authors. Ponsie and Deffenham, in particular, describe two kinds. Three months were not only employed as auxiliary, but even sometimes as curative ones, when it was impossible to use neither. To each bandage, two compartments are too convenient in their effect, M. Lonsie prefers a simple linen roller, one inch wide, three or four long, and rolled up into two or three folds. He begins with applying the body of this bandage to the inside of the fissure; he supports the two heads from before backwards, above, below, between the upper part of the bandage and the incisions, in order to let them cross on the nose of the nose, and then pass downwards again. The assistant who supports the head, and pushes downwards the cheeks, must lift up the ends of his fingers at the place of which, on each side, a small portion is to be put. This being covered, and pushed from behind thoroughly the roller, will constantly perform the office of the assistant's fingers, who is to continue to support the apparatus until it is all completely applied. The longest of the two heads of the roller being six or seven inches over the lip, proceeds two parallel spaces; the foremost of the shortest one is divided into two parts, as far as the end. The two little narrow bands in which a transverse piece then passes through the openings of the former, and cross upon the middle of the lip. The ends of the roller being carried from behind backwards, are then to be applied to cross each on the nose of the nose, where the shortest is to be. The remainder of the band is to be employed in making turns round the head. This bandage may be still more readily fixed by means of a piece of tape, which is to pass the forehead over the upper fissure, and be passed at each end to the intercommissures of the upper; while a second piece of tape is to cross the first one at the top of the head, and also to be attached to its extremity to the middle bandage, and the compresses placed under the typical motion, for the purpose of pushing forward the cheeks.

This bandage is extremely simple, and would answer well as an auxiliary to the twisted suture. I think this last, means well always to be the favourite of the practical surgeon, because the desired effect can be produced by a with much less trouble than must be made with the bandage, in order to render the operation of the latter sufficiently certain. Besides, as I have noticed, M. Lonsie himself mostly made one stick over the red part of the lip, so that he cannot be said to have trusted altogether to the bandage.

What has been said respecting the operation for the hare-lip, is equally applicable, not only to the treatment of cancer of the lip, but also to that of aneurysm, carbuncles, or lacrimations of this part, from any cause whatsoever. We shall only remark, that in a recent wound, all the surgeon has to do, is to apply the twisted suture and adhesive plaster without delay.

When there is a fissure in the lower border of the roof of the mouth, it slowly diminishes, and gradually closes, after the hare-lip is cured. But this does not always happen, and when the parts remain so considerably separated as to obstruct speech and deglutition, or cause any other inconvenience, a plate of gold or silver, exactly adapted to the arch of the palate, and secured by means of a piece of surgical bandage at its corners, and introduced into the flesh, may sometimes be readily employed. When the opening is of considerable size and very dry before, being tied, the moisture of the adjacent parts will make it speedily, and in many cases be sufficient to keep it in its situation, so as readily to facilitate speaking and swallowing. Nevertheless, however, the fissure is so shaped that the tongue cannot be fixed in it: this frequently happens when the opening makes very much towards the front of the jaw. In such cases, it has been proposed to fix a plate of gold by means of openings covered with the same material. Plaster, which is cheaper, might be used for the same purpose. The subject, however, of artificial plates is one in which much mechanical ingenuity may be usefully exerted, and it can hardly be supposed that I should have so more than five or six

[illegible]

The operation of nephrectomy, or pelvic exstrophy was first performed in 1894, by Professor Wadsworth, of India, and soon afterward repeated in Paris by M. Tonn.

Professor Wardner, of Harvard University, was the first to perform it in this country, and Professor Florence, of New-York, has since repeated it on a young man, *et. 55*, for a frightful congenital disease of the palate, with very unfavourable success. This latter case is reported at length in the New-York Medical and Surgical Journal, for April, 1827.—(Root.)

HEAD, VENTRALS, WRIST. From the capacity of parts of which the body is composed, than their structure, resistance, and uses, inferences draw as to its potential endurance feasible of much more significance than the same kind of life can prove, when inferences the only most legitimate of the role of the body. One principal notion of the finger in these cases depends upon the free communication between the vessels of the pericardium and those of the dura mater, through the spine of the skull; for when interference is killed in the lower membrane, it may extend itself to the latter. According to Sir Astley Cooper, there are three vessels in which vessels of the body may induce fatal compression: 1st, by producing what is called an aneurysmal inflammation to the head; 2dly, by producing aneurysmal expansion under the tendons of the vertebral arteries; 3dly, by rendering a single fracture compound, so as to cause more extensive inflammation of the third matter.—*Lectures*, vol. 1, p. 293. The latter observation, as far as my intimate acquaintance is concerned, deserves the serious consideration of the practitioner; for in the great hospital where I was educated, and in all the practices which I have seen in the army and navy, as in biology of this kind was ever supposed between ordinary compound fractures and those of the cranium. If the doctrine be correct, it seems another weighty argument

against the method of cutting down to a fracture of the limb without benefit thereby.

These records of the early life, infancy, and adult years continued to increase, owing to friends and acquaintances; but they are not entirely devoid of danger, in proof of which, Sir Astley Cooper mentions the case of a lady of rank in the country who had from the removal of an exposed tumour of the scalp—(Gazette, vol. i., p. 260.) Finding over these cases, however, were generally lost as well the generality of cuts in the skin of other parts of the body, and perhaps in some cases of treatment, Mr. Pott proceeds to mention a numerous and assorted wounds. "The arms may be subject to two kinds, viz. those in which the laceration, though more or less deeply divided, still keeps in some one situation, and is not supposed nor required to be exposed to any considerable distance beyond the borders of the wound, and those in which it is more severely divided from the parts it ought to cover. The arms of this, if simple, and not combined with the symptoms or appearances of any other accident, does not require any particular or different treatment from what the same kind of wounds require on all other parts;" but with respect to those in which the wound is separated and detached from the parts it ought to cover, Mr. Pott makes no attempt of pointing to his opinion, that its protraction might always be interrupted, unless it be so open as to be immediately closed, or there are manifest general symptoms of ill success; in former days, the practice of the incision and detached scalp was the general practice; but Mr. Pott had so often made the experience of attempting to preserve the skin piece, and in this manner, that he recommended it as a thing always to be attempted, even though a part of the cranium were exposed here.

Here I may remark that all governments are not badly served by getting away the study, even in the circumstances, in which such premises were entered in. For, by so doing, the student writer will not be exposed to any necessity to study the same. However, as it is impossible for him to take the course of his study, which never can be with certainty fixed; and as the execution of the part is possible, the production of the board, even if something must follow, such operations as, in every point of view, would be wrong. With respect to other matters, it is true, the execution of the same, and even the application of the principle, never require any of the study to be set aside. (See *See* *See*.)

Notwithstanding Mr. Post asserts that the majority of farmers for raising certain important breeds of the sheep, the best practitioners of the process, do generally employ only stocking plow. Sometimes the loosened sump will surge with the plow, from which it is then and sometimes, and there will be no other loss than what arises from the disarrangement of breaking the top of the mound into smooth and continuous contact, the sort of which can most be made in practice. Sometimes such perfect reason is not to be attained, in which case, matter will be forced and collected in those places where the plow is not used; but this does not necessarily make any difference in the general intention as to the event, that matter may easily be discharged by one or two fresh openings made with a harrow; the land will be greatly improved, the natural contour; and the same will be very soon corrected by a few hard seasons.

In some cases (see Post should be described in whole unoccupied place will make perfectly, and give little or no trouble, especially in young and healthy persons. In some, the uterus will take place in some parts and not in others (see Brode, in *Ann. N.Y. Hosp.*, vol. 14, p. 385); and consequently there will be found, and require to be discharged, perhaps in several different parts, and in some particular conditions, and habits, there will be no need at all. The fact of the uterus in the early stages will induce and become strongly, a pathological quantity of matter will be collected, and, perhaps, the uterus will be decided. But even in the case of this, which does not very often happen, where the uterus is found, and in almost the same, which has been the case of more simple leucorrhoea and endometritis.

If the surgeon will not be too soon or too much alarmed, not in a hurry to cut, he will often find the case much more favorable than he may at first imagine: let him take care to keep the inflammation under by proper means, let him give passage to the matter as freely and fully formed, and the sloughs perfectly separated, and when this is accomplished, let him make a proper use of dependent openings for the discharge of them, and let him by bandage and other proper management, keep the parts in constant contact with each other, and he will often find, that although he was told in his first opinion of procuring immediate union, yet he will frequently succeed in this his second: he will yet save the scalp, shorten the cure, and prevent the great deformity attendant (particularly in women) not only from the scalp, but from the total loss of hair.

This union may often be procured, even though the infection should have been perfectly absorbed by the accident; and it is true, not only though it should have been stopped at its perichondrium at first (see *abscesses in the forehead of the head*, case vi), but even if that perichondrium should have become sloughy and cast off, as Mr. Pott has often seen.

Excitation from a fracture, laid bare by external wounds, and to which no other agency has been done than merely stripping it of its covering, is a circumstance (see *Pott*) which would not so often happen if it was not taken for granted that it must be, and the bone treated according to such supposition. The soft parts, instead of the bones of children and young people will frequently furnish an instrument, which will cover their surface, and under explanation give opportunity (see also *fracture*, in *Med. Chir. Trans.* vol. II, p. 409); and even in those of mature age, and in whom the bones are still harder, excitation is not so often the effect of art as the absorption of matter, and produced by a method of dressing not suited to accomplish such end, and a large proportion of it being necessary. Sometimes, indeed, it happens that a small scale will necessarily separate, and the case cannot be perfectly healed till such separation has been made; but this kind of excitation will be very usual and then in proportion to that produced by art, that is, that produced by dressing the surface of the bone bare with spirituous functions, &c.

Small wounds, that is, such as are made by instruments or bodies which pierce or puncture rather than cut, are in general more apt to become inflamed and to give trouble than those which are larger; and in this part particularly, are sometimes attended with so high inflammation, and with such symptoms, as alarm both patient and surgeon.

If the wound affects the cellular membrane only, and has not reached the aponeurosis or perichondrium, the inflammation and tumor affect the whole head and face, the skin of which wears a yellowish cast, and is sometimes thickened with small bladders, containing the same colored serum; it reserves the impetuosity of the pulse, and becomes pale for a moment, but returns immediately to its inflamed colour; it is not very painful to the touch, and the eyes and ears are always suspended in the tumefaction, the fever of which is sometimes so distended as to be attended with a feverish heat and third generally accompany it; the patient is restless, has a quick pulse, and most commonly a nausea and inclination to vomit.

This disease generally happens to persons of intense habit, and is indeed an inflammation of the erysipelas kind; it is sometimes alarming to look at, but is run often attended with danger. The wound does indeed receive look well, and exude a healthy discharge, while the fever continues, but still it has nothing threatening in its appearance, none of that look which bespeaks a mortal result; the scalp continues to adhere freely to the skull, and the patient does not complain of that oppressive pain, nor is he afflicted with that burning tenderness which generally attends acute inflammation of the brain.

Phlebotomy, leeches, purges, and the use of the common antiphlogistic medicines, particularly those of the neutral kind, generally remove it in a short time. When the inflammation is gone off, it leaves on the skin for a little while a yellowish tinge and a dry scurf, and, upon the disappearance of the disease, the wound transparently recovers a healthy aspect, and soon bestows some very distinct trouble. I do not remember yet the

exhibition of bark, in this form of erysipelas, as ever productive of any decided benefit.

Wounds and contusions of the head, which affect the brain and its membranes, are also subject to an erysipelas kind of swelling and inflammation; but it is very different both in its character and consequences from the preceding.

In this (which is one of the effects of inflammation of the meninges), the local symptoms are much higher, the pulse harder and more frequent, the anxiety and restlessness extremely troubling, the pain in the head excessive; and in this kind of appearance, in these circumstances, most frequently the immediate precursor of matter forming between the brain and dura mater, it is generally attended with irregular convulsions, which are not followed by a critical crisis, nor afford any relief to the patient. To which it may be added, that in the former case the erysipelas generally appears within the first three or four days; whereas, in the latter, it seldom comes on till several days after the accident, when the symptomatic fever is got to some height. In the simple erysipelas, although the wound is crude and unhealed, yet it has no other mark of mischief; the perichondrium adheres firmly to the skull, and upon the cessation of the fever, all appearance becomes immediately favourable. In that which accompanies injury done to the dura mater, the wound has only a spongy, glazed, unhealthy aspect, but the perforations in its neighbourhood separate spontaneously from the bone, and quite all cohesion with it. As death, even in an accident proceeding from a laceration of the skull, and not indicating any mischief beyond itself, the latter is a symptom or a part of a disease, which is occasioned by injury done to the membrane of the brain: one part only is killed to the point, and almost always ends well; the other implies great hazard, and most generally ends fatally. It is therefore hardly necessary to say, that it behoves every practitioner to be careful in distinguishing these from each other.

If the wound be a small one, and has passed through the cellular membrane to the aponeurosis and perichondrium, it is sometimes attended with very dangerous, and even very alarming symptoms, but which now look a different case, and are very distinguishable from what has been just mentioned.

In this, the inflamed scalp does not rise into that degree of tumefaction as in the erysipelas, neither does it pit, or retain the depression of the finger on an elevation. It is of a deep red colour, marked with the yellow tinge of the erysipelas; it appears tense, and is extremely painful to the touch: so it is not an adhesion of the cellular membrane, and as the bone and the erysipelas are not covered by the parts in which the wound is indicated, they are seldom if ever comprehended in the tumour, though they may partake of the general inflammation of the skin; it is generally attended with acute pain in the head, and such a degree of fever as prevents sleep, and sometimes brings on a delirium.

A patient in these circumstances will often more feel excruciations by phlebotomy than one following upon an erysipelas: the use of warm fomentation is required in both, in order to keep the skin clean and perspirable; but as emollient cataplasms, which is generally advised in the former, may in this latter case be good with great advantage.

When the symptoms are not very pressing, see the best very inflammatory method will prove sufficient; but it sometimes happens that the scalp is so tight, the pain so great, and the symptomatic fever so high, that by waiting for the slow effect of such means, the patient runs a risk from the continuance of the fever, or else the increased aponeurosis and perichondrium, becoming sloughy, produce an abscess, and involve the eye both before and afterwards. A division of the wounded part by a sharp instrument down to the bone, about half an inch or an inch in length, will most constantly remove all the bad symptoms, and, if it be done in time, will render every thing else unnecessary. We have perceived that, in this form of inflammation, the practice of making an incision had the sanction of Pott; but the extent of the wound recommended is moderate, and very different from what has been recently proposed for dangerous erysipelas of the scalp. With respect to the good effects of such an incision Dr. Keil considers this greatly exaggerated.

gerated by anæmia; and while he admits that they are useful when the inflammation extends under the aponeurosis, he is not inclined to estimate it as a right proceeding in other instances.—(*See Clin. Lect. on the Brain*, p. 8.)

Thus Mr. Pott was of opinion, that the difference of the symptoms in the temporary cases depended upon whether the wound only affected the skin and cellular membrane or penetrated more deeply to the aponeurosis and pericranium; a doctrine which has been justly regarded as questionable. With respect to the observation that it is a precursor of the aponeurosis swelling, he is confined, within the limits of this tissue, and does not extend to the sinus and eyelids; it is a symptom which Desault thought arose rather from superficial inflammation than the observation of writers. The doctrine, indeed, must appear doubtful, when it is considered, 1st, That the aponeurosis and pericranium are parts of scarcely any sensibility. 2dly, That the opinion had the origin at a period when these parts were supposed to be highly sensible. 3dly, That in other parts of the body, a wound in which a flaccid or the pericranium is wounded is rarely attended with the above-described severe symptoms. 4thly, That now the wounds which affect only the skin and cellular membrane, and yet these symptoms occur even with a pleuro-pneumonia thoracis. 5thly, On the contrary, in other instances, in which the aponeurosis and pericranium are undoubtedly wounded, no bad symptoms at all take place. 6thly, These symptoms may almost always be removed by the exhibition of tannic acid anodyne.—(*See Clin. Lect. on Desault*, p. 8.) In the case often named inflammation of the fluids, after bleeding, it is not the fluids itself which is the real and chief seat of the pain, inflammation, &c., but the subjacent cellular membrane and cranium. The theory of Desault is, that the erysipelas infections of the scalp so frequent after injuries of the head, are connected with disorder of the functions of the liver, produced by such accidents. Yet it is difficult to understand why a more profuse of the scalp should cause this disorder of the liver more commonly than the same kind of wound of any other superficial part of the body.

The injuries to which the scalp is liable from contusion, or appearances produced as it by such general causes, may be divided into those in which the mischief is confined merely to the scalp, and those in which other parts are interested.

The former, which only come under our present consideration, are not indeed as numerous, considered absolutely. The latter is rather very readily distinguished, or the extravasated blood causing it is easily got rid of by a small opening. 1. I. First free, and afterward free, particularly noticed this case, on account of an accidental circumstance which somewhat interests it, and renders it likely to be very much mistaken.

When the scalp-membrane is very much lacerated, it often happens that a quantity of extravasated blood, frequently forms a tumour, easily distinguishable from all others, and generally very early cured. But it also sometimes happens, that this kind of tumour proves to the fingers of an unskilled or unfeeling surgeon a sensation so like to that of a fracture, with depression of the cranium, as may be easily mistaken. Now if, upon such supposition, a surgeon needlessly makes an incision into the tumour, so that he give the patient a great deal of unnecessary pain, and for that reason risk some loss of his own character.

The touch is in this case so liable to deception, that surgeons should always be led to other circumstances and symptoms, before an opinion is given.

If a person with such tumour, occasioned by a blow, and attended with such symptoms, and, yet, has any complaint which seems to be the effect of pressure made on the brain or nerves, or of any mischief done in the parts within the cranium, the division of the scalp is often inquired into the state of the skull, is sight and necessary; but if there are no such general symptoms, and the patient is in every respect perfectly tranquil, the best of something like a fracture will not occasion any valuable such operations, since it will often be found that such sensation is a deception, and that, when the extravasated fluid is removed, or dissipated, the tumour is perfectly sound and unaltered.—(Pott.)

With the exception of instances in which the dura mater separates from a blow on the head, and the symptoms are such as to require the trepan, or other operations in which an abundant supply of blood is necessary, in a large quantity of blood is effused in the same manner, none of the cases which have been here mentioned can justify making incisions in the scalp. When blood is superadded under the scalp, the incision need not be too extensive with me, but, as the incision there is a violent electrolytic blood. The remedy with which an effusion of blood under the scalp is disposed as well illustrated in a case mentioned by Mr. Brooke. He was consulted about a young gentleman, under whose scalp an effusion of blood exuded from the superciliary ridges to the top of the head, and from ear to ear. The blood appeared to be in a fluid state, and was so copious, that no part of the cranium could be felt. In a few weeks, and without aid of a cold lotion, the whole tumour was absorbed. Mr. Brooke observes, that whenever high in the vessel required, it must have continued to bleed a considerable time, in order to produce so large an extravasation. I have seen three or four times nearly as remarkable as the preceding, and having a similar favourable termination under the use of simple German Saline and occasional purgatives. In one instance, attended by Mr. Brooke, he succeeded in preventing the effusion from producing the effects described in his last case, by means of pressure applied to the point where the flow had been received, and a vessel tied.—(*See Med. Cas. Trans.* vol. 13, p. 386.)

The utility of an antiseptic lotion, was suggested by Pott to be an inflammation of the aponeurosis is a less questionable, as far as it is done under the idea of merely obtaining rest, without there being any matter to be discharged. Incisions, especially for the purpose of exposing the bone, are only right as a prophylactic step to keep the scalp, when the necessity for the operation is indicated by decided and urgent symptoms of pressure on the brain. Now such pressure, in any of the symptoms above treated of, can only arise from a suppuration under the skull, a subject which we presently have to consider.

Dr. Ferrius, in his truly practical work, has very properly advised surgeons not to be content with opening away a little of the bone around the injury, but always to divide the bone down to the proper extent. This proceeding, which is perfectly harmless as long as it is generally right that the nature of coming the scalp, which has been too frequently employed without any rational aim. The free removal of the hair during which is the most effect of the scalp is a very simple and easy part of the operation, and the hair being removed, the scalp is left in a state of rest, and the pressure will have a more correct notion of the extent of the injury, and the patient than he might otherwise have imagined, and is more strict in his rules of treatment. Now, instead of a dissection of the skull, sometimes we should be very distrustful of the necessity of the trepan, and to escape otherwise, while consulting with the eye, are frequently deceived after its power, and the surgeon being now aware of the extent and situation of the mischief, instead of treating as he is bound to regard the treatment. In short, at Dr. Ferrius has observed, "independent of the more accurate view thus presented, we facilitate the application of trepan, if they may be found necessary, and of a more certain advantage on all occasions, viz., and application."

It affords the possibility of planning as to be able to discover as good a surgeon as Dr. Ferrius, among the advocates of Schuwaloff's plan of letting the head well exposed and covered with cloths that with a very old fellow; a practice which the latter himself, always always adopted, whether a subcutaneous or extracranial injury of the part had the appearance of being within or not. "As soon as the patient was brought to the hospital, with a wound of the head, whether the injury was supposed to be not (says Schuwaloff), I attended the part to be immediately removed, and after the necessary incision, applied dressings. Patients orders of blood were immediately away, and the cranium, in last instance, rejected, according to circumstances, when it fell down within the space of twelve or four hours. The patient now generally became better, and the determination of blood in the head removed. After the pressure and the release of the head, such cases, depend on the cold nature of the matter applied, were less, and more."

every brain. These discharges kept in their place with the lamellae called the great cerebral—(see standard age.) As internal medicines, the nitrates of potassa, neutral salts, and emetics and stimulating diuretics, and gentle aperients were given. These means were employed, both in single injuries and in those where the bones were depressed, and the fissures and fractures were accompanied with rational contractions (twitchings, cramps, paralytic, and other local symptoms), and even in cases where the use of the machine was indispensable, the practice was continued until the case was cured. (See *Chir. Hæmorrhæmages*, 3, l. p. 124.)

Ichterus was led to try this practice in the great breadth which he had seen afforded by the application of cold water to the head in cases of trauma, attended with great distension of blood in the brain. And in order to increase the efficacy of the water, he added to every five gallons of a two quarts of vinegar, six ounces of ether, and eight of the mixture of ammonia. This mixture was then presented for use in a cold place—(Vol. vi. p. 113.) Or, in order to avoid ourselves fully of the frigorific effects of this mixture, it should be prepared, as Dr. Hunter observes, in small quantities, and used immediately before use; or, as temperature has risen; or, if it should be applied in a warmer place, it should be applied in a half filled bladder, or other empty dipped in cold water, will often answer every purpose—(See *Military Surgery*, p. 223, ed. 2.) Dr. Hunter mentions one important fact, in consequence of cold applications, antiseptics, and saline purgatives, preceded by the common blood pill, and assisted with quiet and abstinence. viz. by such means, "these troublesome puffiness, enlargements and erysipelas of the face of the scalp, which are often noticed in trauma, are prevented, and where the erysipelas plan is duly observed, the extensive and formidable erysipelas of the face, as common formerly, are rare and seldom as frequent in military hospitals."

5. Effects of Contusion on the Dura Mater and Pons within the Skull.

In contusion of bones, lacerations, and other shocks, either blood may be effused under the membrane, or is disseminated and suppuration of the dura mater may arise. The best description of the latter case is that delivered by Mr. Pott.

Brain and severe strokes on the middle part of the brain, with delirium were the victims, he says, are most frequently followed by this kind of mischief: the cause of the skull wound, which strains the injury, rupture and hemorrhage, and in consequence of such interruption, there the performance separates from the outside of the part of the bone which covers the brain, and the dura mater from the inside, the latter of which immediately, some after, such inflammation, becomes bloody and, and sometimes matter, which is rather long in coming because the said membrane and the cranium, not having an external coat, referring to escape as he described, brings on a train of very terrible symptoms, and in very frequent cause of destruction. The effect of this kind of mischief is frequently noticed in the vessels remaining the dura mater to the cranium, in which much matter is retained in the said membrane; but sometimes the matter forces its consequence of such violence in front on the surface of the brain, or between the patient and matter, as well as on the surface of the latter; or, perhaps, in all these three situations at the same time.

The difference of this kind of disease from either an extravasation of blood or a contusion of the brain is great and obvious. "All the symptoms produced by extravasation are such as proceed from pressure upon the brain and vessels, and obstruction to the circulation of the blood through the brain; stupor, loss of sense and voluntary motion, insensibility and incoherence of sense and respiration, &c., and which lose importance in remark; if the effusion be of any considerable, these symptoms appear immediately, or very soon after the accident."

The symptoms attending an inflamed or bloody state of the membrane, in consequence of external violence, are very different; they are all of the hectic kind, and never at first imply any treatment peculiar to such

any pain in the head, restlessness, want of sleep, frequent and hard pulse, hot and dry skin, flushed countenance, inflamed eyes, bowels, vomiting, rigor; and, towards the end, convulsions and delirium. "And none of these appear at first, that is, immediately after the accident; children could come days are passed."

Thus the observation, made by Pott, is one that is well worthy of the practitioner's constant recollection, just as verily, every his patient secure the worst, and suggest the very use of the only means by which a recovery can be effected. Thus, as for Albert Cooper asserts, the time when inflammation of the brain first, it may be said, of the membrane follows the violence is generally about a week, rarely sooner. "Frequently it does not come on till a fortnight or three weeks after the injury; and even more time sometimes before the patient is quite well, or ought to deviate from a strict and temperate regimen. In confirmation of this remark, a case is mentioned, where the subject to keep the forehead began brought on a fatal attack of inflammation of the brain, as late as four months after the receipt of a blow in the head—(See *Chir. Hæmorrhæmages*, 3, l. p. 124.)

One set of cases of symptoms is produced by an extravasation of blood, making pressure on the brain and origin of the nerves, so as to impair or abolish voluntary motion and the senses; the other is caused by the inflammation of the state of the membrane covering the brain, and seldom affects the organs of sense, and the latter end of the disease, that is, when a considerable quantity of matter is formed, which matter must prove like any other kind.

If there be neither fracture nor fracture of the skull, nor extravasation of blood immediately under the skull, and the only to further consideration, if the wound, the mischief is seldom discovered or attended to for some few days. The first attack is generally by pain in the part which received the blow. This pain, though beginning in that point, is soon extended all over the head, and is attended with a lagging, or disposition of strength and spirit, which are soon followed by a sense and insensibility to voice, a vertigo or giddiness, a gait and fixed pulse, and in propensity of sleeping, at least quietly. A day or two after this attack, if no means preventive of inflammation are used, the part affected generally swells, and becomes puff and tender, but not painful; neither does the matter arise to any considerable height, nor spread to any great extent; if this kind of part of the scalp be then divided, the performance will be found of a darkish hue, and either glass detached or very easily separated from the skull, between which and it will be found a small quantity of dark-colored blood.

If the disorder has made such progress that the part affected is quite separated and detached from the skull, the latter will even now be found to be somewhat elevated in color from around, healthy bone.

Thus this case the symptoms generally increase gradually and more apparently; the fever increases, the skin becomes hot, the pulse quicker and harder, the sleep more disturbed, the countenance and countenance more fuliginous; and to these are generally added irregularities, which are not followed by any critical event, and which, instead of relieving the patient, and consequently is not relieving. If the scalp has not been divided or removed, and the symptoms are thus advanced, the alteration of the color of the bone will be found to be more remarkable; it will be found to be white and red, dry than a healthy skin, or, as Pott says, has very little color; it will be found to be more like a dead bone: the surface of the skull between it and the perforation will also, in the same time, be found to be more of a healthy, and the said membrane will have a more thin, depressed aspect.

In this state of matters, if the dura mater is divided, it will be found to be detached from the inside of the cranium, to have lost its bright surface, and to be, as it were, covered over with a kind of matter, or with matter, but not with blood. Every body after this point, all the symptoms are increased, and become more violent; the strength decreases, the eyes are more frequent, and at last convulsive motions, attended as these with delirium, at others with paroxysms of extreme stupor, finish the tragedy.

If the scalp has not been divided all this part of time, and it is to come later, a very different appearance of the skull will be found lying on the bare cranium.

whose appearance will be still more unlike to the healthy natural one; if the loss be now performed, matter will be found between it and the dura mater, generally in considerable quantity, but different in different cases and circumstances. Sometimes it will be in great abundance, and diffused over a very large part of the membrane; and sometimes the quantity will be less, and consequently the space which it occupies smaller. Sometimes it lies only on the outer surface of the dura mater; and sometimes it is between it and the piamater, or also even in the substance of the brain, or within the substance of it, &c.

As the inflammation and separation of the dura mater is an immediate consequence of the violence, so neither are the symptoms immediate, although some days have passed, the fever at first is slight, but increases gradually; as the inflammation becomes more and more diminished, all the febrile symptoms are diminished; the formation of matter diminishes, rigors, tremors and tremors, with which it usually is collected in large abscesses, diminish, and lastly, the patient recovers.

When the scalp has been wounded, Mr. Pott observes, the wound will for some time have the same appearance as a mere simple wound of the part, attended with other disordered, most likely, it will, like this, at first discharge in this nature or glossy and then begin to suppurate; it will discharge, begin to suppurate, and last perfectly well; but after a few days, as these febrile symptoms will increase; the wound will lose its first corruption and granulated surface; it will become very glossy and bloody; instead of good matter, it will discharge only a thin discoloured serum; the film with which it is dressed, instead of coming off easily (as in a healthy suppurating sore), will stick to all parts of it; and the perforations instead of adhering firmly to the bone, will separate from it, it will recede at some distance from the edge.

"This situation in the face and countenance of the face is produced partly by the diseased state of the parts underneath the skull; which is a continuation of the inflammation in support of the diseased skull, and is characteristically proved, by observing that this diseased aspect of the face and countenance, separation of the perforations, the always confined to the part which causes the altered or injured position of the dissection, and which at all affect all part of the scalp; say, if it has by accident been wounded at any other part, or a portion has been removed from any part where an injury has been done to the dura mater, or such separation will happen, the detachment above said always correspond to this below, and be found to where it is.

The first appearance of alteration in the wound immediately depends on the febrile attack; and as the febrile symptoms subside, the more becomes white and more; that is, digestive matter and more from a healthy, healthy aspect.

Through the whole time from the first attack of the fever to the last and fatal period, an attentive observer will remark the gradual alterations of the colour of the face, if it be fair. At first, it will be found to be white and more dry than the natural one; and as the symptoms increase, and either matter is collected on the dura mater becomes bloody, the face becomes more and more to a kind of purple, like or white as yellow; and it may also be white while in this place is found, that if the face was on or very hot in a patient, and the patient young, the heat will be offensive to the air, it may be so to let through a loose, yellow, ill-natured fungus; at which time, also, a great increase in the patient's heat and flow is attended with an erysipelas.

In these cases in which the scalp is very little injured in the brain, and in which there is no wound, but any immediate striking symptoms of suppuration, the patient will have no such symptoms, although matter may suppurate, with some few days are past. At the end of the symptoms, then, he is generally attacked by the symptoms already treated; these are not growing of first, but they may increase so with a degree, so as to kill the patient, where, where it will not, but when this is the case, the patient frequently suffers from what we call a first indication of matter, and prevents with attempts being made, and such attempts being taken of him, as might prevent the formation of matter.

But if the symptoms are so increased as to cause or claim our early regard, very useful information may from thence be collected, for whether the scalp be con-

siderably injured, or whether it be found necessary to divide it for the discharge of extravasated blood, or if necessary of some suppuration or more violent symptoms, the state of the perforations may be thereby ascertained and more certainly known; if in the place of such better, the perforations be found spontaneously detached from the skull, having a quantity of discoloured serum between them under the tanned part, in the manner already mentioned, it may be regarded as a very certain indication, either that the dura mater is beginning to separate in the more interior, or that, if some perforations be not immediately used, it will not suffer; that is, it will inflame, separate from the skull and give room for a collection of matter between them. And with regard to the wound itself, whether it is situated at the base of the cranium, or elsewhere generally, it is the same thing; if the situation of it is superficial, or is found, if the signs of it immediately give their influence to the bone, and the febrile symptoms are at the same time making their attack, these circumstances will serve to convey the same information, and to prove the same thing.

The particular effect of continued suppuration and its effect on the brain, and on the general health, is not to be considered, as well as an extravasation of blood, in cases where the bone is more, and, in some other kind, at these do either by the nature of the connection of the individual matter. All this is matter of observation, and the other circumstances, we will not omit, the symptoms of separation of the dura mater, in consequence of a severe blow, or other causes, is attended by a separation between the cranium and the matter, a circumstance extremely well worth attending to at distinct and unexpressed fracture of the skull, because it is from this circumstance, probably, that the fatal symptoms and the patient in such cases arise.

It is a very common thing for a patient to be brought to bed to produce some disturbance and symptoms which after a short space of time disappear, and the patient perfectly well. A slight pain in the head, a little swelling of the face, a vertigo and nausea, sometimes immediately follow such a wound, but it is not common many hours, especially if any treatment has been used. There are not uncommonly some to a light continuation of the fever, which having suffered no material injury thereby, soon ceases. But if after an interval of some time, the same symptoms are renewed, if the patient, having been left, becomes more feverish and restless, and that ending in not passing; if he complains of being hungry and vomits, sleeps disturbedly, loses his appetite, has a hot skin, a hard, quick pulse, and a flushed, heated countenance, and a further irregularity of his countenance, and has been productive of these, the prognosis must certainly be alarming, and that most probably under the skull.

If the symptoms of pressure, such as vomiting and of some, watery matter, for, after some time after the head has suffered injury the patient will have the head so much probably supply an effusion of a fluid somewhere; this effusion may be in the substance of the brain, in its ventricles between its membranes, or in the volume of the membranes, and which of these is the real situation of such extravasation it is matter of great uncertainty, none of them being attended with any peculiar mark or sign, and one may be proved upon as pointing it out precisely, but the examination of the dura mater, and the situation of matter between it and the skull, in consequence of corruption, is generally supposed to be the best way. Mr. Pott has happily been known to find a large, irregular, indurated tumour of the dura mater, a spontaneous separation of the perforations from the skull, and such a patient.

These appearances, therefore, following a blow on the head, and attended with nausea, vomiting, weakness, quick pulse, fever, and slight, irregular shivering, do almost certainly indicate an effused very gross, and yet either forming or formed between it and the cranium.

By detachment of the perforations in the skull, every separation of it from the bone which it should cover. It may be, and often is, red, hot, it is moved off, without any such consequence; the same appearances are violent; whereas that which Mr. Pott calls is appearance, and is produced by the destruction of these vessels to which a new connection with the skull, and by which the communication between a pit

showing the largeness of the ball, till it could be seen internally, and the aperture through which it had passed was not more than twice its size. The brain was every where in contact with the skull, and was everywhere equally compressed. The patient experienced a painful sense of oppression and weight in the head, and, when he inclined his head backwards, was seized with giddiness. The legs were weak tremulously in a strong current with out being on his knees. Larry said that every symptom of compression of the brain was present, though the operation is rather difficult to comprehend, considering that the patient stood up, and almost his posture. As we are the surgeon given by himself of his confidence, that in another circumstance in which I should not be permitted to dwell because it is all violating the honor was not able to interfere in the Russian language, and the operations respecting the skull's surface were made in some other way. The following might be the real state of the symptoms: said in a case of this kind a correct account of them would have been interesting; the ball was plainly contained, by means of a probe, to be of that size of about three inches, and the opening through which it had entered, and that for the purpose of examining it the application of the finger was usually necessary. The fracture was daily brought into view by cutting through the skin, perforations were made with a small hammer in the upper part, and when the removal of the margin of the bone between these perforations the ball, which weighed some three ounces, was easily extracted with the aid of a strong piece of wire and an elevator. A considerable quantity of granulated blood was also brought away when the skull was found with a compression of three or four lines long. As soon as the removal of the bone had been taken away, the part was dressed with a bit of fine linen soaked in warm wine, moistened with sugar, and ointment was placed around, severe compression, and a bandage. With respect to the symptoms of giddiness and other symptoms in the surface of the brain, in which compression or laceration had been, it was not so as to require practice with Larry, or with Schreiner, and the other surgeons. On what principle the causes in all kept up, and whether it was only one or several, are symptoms which were not understood. In whatever way, experience may illustrate these matters, rather it is to add, that the patient was relieved by the treatment, and fell into a quiet sleep for two hours; but in the evening the disease returned, and the work was nearly finished. A considerable quantity of blood was taken from the two apertures and very slowly was not practised at first, some extraordinary. The dressings, which, according to my case, were highly objectionable, were removed, and a large modified poultice applied. Young men, containing a small quantity of tartar emetic, and other antispasmodic medicines were prescribed. The following day the patient's state appeared satisfactory, without the slightest disturbance of the wound, and in the like he perfectly recovered.

The other soldier had been wounded in the left temple with a loaded ball, five days before Larry saw him. The ball of the ball had gone into the cranium through a very narrow breach; the other half broken under the forehead, and had lodged near the posterior pole. The right side of the head was swollen, the wound was unhealed, and the man was in a state of constant agitation. After dressing the wound at the temple, and opening the fracture, Larry discovered the track of the bullet, which had passed through the frontal process, and which he subsequently removed by a craniotomy. At the lower part of the wound, about the middle of the temple, very near the spot where the other portion of the ball was lodged, the whole state of the brain, and a quantity of granulated blood, was easily extracted. The patient, however, was not saved; a hemorrhage, excited by Larry in the operation, having been fatal.

Another case, less often reported, occurred at the hands of the Russians, and with symptoms of depression, not, after death, a picture of a bullet, and a fragment of bone were found under the skull, attended with an internal or external state of the adjacent portion of the brain. Larry very properly expressed his opinion, that this soldier would have had a chance of being saved, had the troops been good.

(See *Med. Repert.* 1814, 4, p. 285, &c.) The practice of trepanning for the removal of balls, situated near a fracture of the skull, within the bony cavity, or lodged among the fragments, or between the two tables filled with matter (see *Encyclopædie de Médecine*, 1814, 4, p. 285, &c.) is not permitted to Larry, for he has been severely injured by other surgeons (see *Mémoires de Médecine*, 1814, 4, p. 285, &c.) but I do not know that he has been attended in his last practice of making a counter-opening in the skull, when the ball is lodged at such a distance from the fracture, as not to be extracted through any perforation made in the vicinity of the original injury. For this a practice which he ventures to try does, that when a ball has entered the cranium, without fracturing the roof of the skull, the case is one requiring the application of the trepan.—*Mémoires de Médecine*, 1814, 4, p. 185. In the 2d vol. of this work (p. 125), the patient with the fracture of a radius, who was struck on the right side of the forehead with a ball, which penetrated the os frontis, and then passed obliquely backwards, between the skull and the dura mater, in the course of the longitudinal suture, so far as the dischordal suture, where it stopped. Larry traced the direction of the ball, by the consideration of an elastic probe, which he used the opening; and measuring the distance between the fracture and the place where he felt the ball, he went down until that part of the skull, beneath which he concluded that the ball was lodged. The bone was then perforated with a large trepan, a good deal of pus was discharged, the ball was extracted, and the patient recovered. One thing here attracts the attention of surgeons: Larry tells us, that a good deal of pus issued as usual as an opening was made in the skull. There were then have been suppurations under the bone, and suppuration and discharge of the dura matter, observations which are not according to fact, by a corresponding supuration in the perforation, and a good quantity of the scalp. This case suggests this place in the forehead, so as to limit the assistance to Larry, in judging of the place where the ball was lodged, and the question of them here carried out by accident, or as we do not, that suppurative may happen between the cranium and dura mater, without any laceration of the pericranium, and justly observe of the scalp, a thing which Richard asserts is proved by daily experience in the House of St. Paul, (see *Chirurgie*, 1814, de Bonnet, 1, 2, p. 29.) Larry, in his 2d vol. (p. 125), says in another case, in which a ball passed the left parietal bone, and lodged near the lambdoid suture. Its situation was detected with the aid of an elastic probe, and pus in consequence of them taking a single copious issue the part. Richard's opinion was made through the scalp, for a small figure discovered. As the symptoms of compression increased, the trepan was applied, so as to remove the bone. A bit of the ball, which was found directly under the perforation, and a good deal of blood was washed from the two openings in the cranium. For a fortnight the case went on favorably; but the patient was then attacked with what Larry terms hospital fever, but which in all probability was inflammation and expropriation of the membrane of the brain, and died.

The necessity of surgery finally increases in proportion to the present liver, or considerable, with balls lodged in the cavity of the cranium. Thus, we are pointed by Parry, where the patient was recovered by means of the trepan, and at the end of six months did so (see *Encyclopædie de Médecine*, 1814, 4, p. 285, &c.). Richard has published another case, where a soldier was shot through the frontal sinus, and the ball was found after death in the medullary substance of the left hemisphere of the brain, half an inch above the ventricle, yet the patient lived three months after the injury, and soon recovered his senses after its removal. For a considerable part of this case he was attended when my father was present. After he was attended with a kind of trepan, and an opening to open his forehead, and fell into a delirium and convulsed state.—(*Schreiner*, *Parry*, 1814, 4, p. 285, &c.) A French soldier, in the battle of Waterloo, was wounded with a musket-ball, which entered at the anterior portion of the squamous suture, lodged in the substance of the brain, and on the fifth day after an enlargement of the wound, and the removal of the

all fragments of bone, was extracted from the posterior lobe of the right hemisphere of the brain, where it was found resting on the arachnoid. Yet during the several previous days, the man, with the exception of a slight headache, and partial destitution of the right extremities to empty perfect health. The case varied well.—(See *Revue Méd. de Paris*, p. 260, vol. 2.) Such more remarkable instances of the duration of life, and even of the absence of any serious symptoms, after great and serious wounds of the brain, and the lodgment of balls, might have led us to; but it will suffice to refer to the instructive history of M. Guigney on the subject, in vol. 1, of the *Mém. de l'Acad. de Chir. Roy.*, and to the account of twenty-two French soldiers, whose wounds, with more or less of the brain, were cut off by surgery. All these men ultimately died; but at first had no a single bad symptom, and performed a quantity of daily labour after being wounded, and one-half of the duration of time.—(See *Papaver, Opuscule de Chir.* p. 41, &c.)

5. Extravasation under its Coverings. Symptoms of Pressure on the Brain, &c.

Mr. Pitt remarks "the shock which the head sometimes receives by falls from a height, by strokes from pointed weapons, &c., does not infrequently excite a lesion in some of the vessels either of the brain or its meninges, and thereby becomes extravasation of the fluid which should circulate through them. This extravasation may be the only complaint produced by the accident; or it may be joined with, or added to, a fracture of the skull. But this is not all; for it may be produced not only when the cranium is perfect, by the blow, but even when no violence of any kind has been offered to or received by the head."

The effused blood may be between the cranium and dura mater; between the latter membrane and the arachnoid; or in the substance of the pia mater, or beneath the arachnoid, or in the substance, or capsule of the brain. The first species of extravasation, which is observed to be always more or less confined, may occur at any part of the skull, but when situated in the brain, is generally fatal. In the second, which is the most common species of extravasation within the dura mater (see *Brain*, in *Art. Chir. Thom.* vol. 14, p. 333), the blood is usually confined about between the dura mater and arachnoid, and on this account, unless its quantity be very considerable, it does not cause any great degree of pressure. In the third example, if the blood be situated in the arachnoid, it is also widely diffused, but it is in the substance or vestibule of the brain, which is rare (*Brain*, vol. 14, p. 333), is circumscribed.—(See *Chir. de Denham*, &c. p. 28.) Sometimes in cases of great violence, as Mr. Pitt has lately observed, the blood is found at the same time in all these different parts.

According to Mr. Brodie's experience, which confirms the observations of Mr. Abernethy, there is longer such extravasation from a rupture of the blood-vessels, by which the dura mater is assumed to be torn, as will produce dangerous pressure on the brain, except when the middle meningeal artery has been lacerated from which vessel the bleeding is sometimes very copious. Mr. Brodie has never seen this after, therefore, except in the circumstances with a fracture running across the bony canal in which it is situated; but he alludes to other cases, recorded by Mr. Latta and Mr. Abernethy, in which no such fracture accompanied the rupture of the vessel.—(See *Art. Chir. Thom.* vol. 14, p. 333.)

Another observation made by Mr. Brodie is, that large extravasations are sometimes found upon the upper surface of the brain, but were frequently at its base, where they are usually the consequence of a rupture of the substance of the brain. This extravasation has never been so extensive, in which the blood does it wounded extravasated between the dura mater and the skull, or between the arachnoid and the brain, as sufficient quantity of fracture with the laceration of the brain.

When the blood is extravasated beneath the skull, the violence which produces the rupture of the vessel usually tears the pia mater, from which state, produced the quantity and pressure of the blood and the force of the respiration to not only grow, but gradually recover and regain its energy. If the first extravasation be

trivial, the patient, after regaining his senses, may only feel a little drowsiness and go to bed. The bleeding from the ruptured blood, continuing, and the pressure on the brain increasing, he becomes more and more insensible, but begins to breathe in a slow, interrupted, convulsive manner. In cases of compression, whether from blood or a depressed portion of the skull, there is a general insensibility; the eyes are half open; the pupils dilated and unresponsive, with loss of the red light of a candle; the action is unsteady; the limbs relaxed; the breathing stertorous; the pulse slow, and, according to Mr. Abernethy, less subject to intermission, than in cases of compression. The amount of convulsive breathing, as this gentleman admits, must not be taken as a proof of their being any compression; the Morgagni's vessels sometimes rupture in persons, in whom the disease was circumscribed, yet no stertor had appeared.

In a part of ventral of the posterior part of the skull, with symptoms, seen by Dr. J. Thomson, the pulse at one time sank as low as 20 strokes in a minute. This eminent publisher, however, is a relation and Mr. Abernethy agree, as to count, by stating that irregularity of the pulse is a frequent effect of any compression of the brain.—(*Report of the Acad.* p. 24, 25.)

Mr. Brodie does not give any positive opinion as to the influence of the pulse in any compression of the brain; but he expresses his belief, that pressure on the brain for the most part affects the action of the heart, not by producing actual obstruction, but by causing its contractions to be either less frequent, or less forcible than natural.—(See *Art. Chir. Thom.* vol. 14, p. 333.) In this opinion referred to in Dr. Thomson's report, some instances undoubtedly arise from the pressure of portions of the skull, forced towards upon the brain. But in a very dangerous instance, but Dr. Thomson gave no other than a few examples after the depressed part of the bone had been elevated, and the extravasation removed.—(P. 34.) Sometimes, I am inclined to regard, with Brodie, rather as a symptom of rupture of the brain, than of compression.—(See *Art. Chir. Thom.* vol. 14, p. 333.)

Mr. Brodie, somewhat in the way of the necessarily partly published in the foregoing work, considers a compressible, whether circumscribed within the capsule, or to be applied as the consequence of a simple pressure on the brain. We had then seen, a very long course of protracted and continued time, when there is no pressure; and whenever he did meet them, he was attracted to depression of the skull, and increased blood, and less afterward had the opportunity of ascertaining the exact nature of the injury, the pressure has always been found to be increased with blood or laceration of the substance of the brain. The compressible substance to which Mr. Brodie alludes, he particularly describes as slight and partial, and different from the more violent and general instances.—(See *Art. Chir. Thom.* vol. 14, p. 333.)

Indeed, the difficulty of the diagnosis in many cases may be well conceived by what Dr. Hennen remarks in his practice; viz. that in some instances the pulse was continued, in others dilated, where the injury was nearly of a similar nature, and again, while sometimes, in the bony part, one part was dilated, and the other much contracted. He saw, also, frequently one on one side, and compression in the other, when the injury had been on the forehead, and the same when it had been on the occiput.—(P. 34, 35, 36.)

Mr. Brodie has seen the pupils dilate with the compression, and contract with the removal of it, though the patient lay in a state of complete insensibility, and did not seem to be at all conscious of the improvement made on the pupil. He admits, however, that this is a rare occurrence, and that, when the other symptoms of pressure are present, the pupils are generally dilated and unresponsive, and much dilated, though sometimes contracted. Every purpose of inspection must be aware of another observation mentioned by the same author; namely, that it is not uncommon for the pupils to remain for a time in a state of contraction, though becoming gradually contracted, and after remaining so for longer or shorter time, to become again dilated; these changes taking place independently of light and darkness. When the pupils have been fixed, Mr. Brodie has frequently known them to become contracted after the abstraction of blood; the diameter

blood is extravasated on the surface of the dura mater, he recommends the blood to be more freely drawn away. He holds this opinion in the case of a vessel which he has opened, where a more liberal opening did not give a sufficient supply of blood to the apparatus that rested on the patient's head. (*Med. Chir. Trans.*, vol. 14, p. 326.)

In the treatment of convulsions from extravasation, Sir Ashley Cooper joins the propriety of symptoms as recommending first depletion, in order to prevent inflammation; the vessels, he says, are to be opened, and the matter kept very quiet. "If there be a tumor, indicating the spot at which the injury has been sustained, you may trepanne with every other vessel has been tried satisfactorily. If a secondary tumor, and the symptoms do not yield to depletion, you will require to seek an explanation." (*Lectures*, p. 228.)

All cases of pressure on the brain are attended with a kind of inflammation of this organ and its coverings. The disease may be viewed as much as possible by applying cold vesicles to the head, and employing fire and repeated bleeding, leeches, cupping, blister, purgatives, and other antiphlogistic means. After the swelling has been controlled, more time should be applied to the head, and the calvaria opened.

Examination of symptoms in this affec-

It is observed by Mr. Ford that "very alarming symptoms, delayed symptoms of the most fatal consequences, are found to attend great vascular disease of the brain; and upon the structure examination both of the living and the dead, cerebral tumors, hemorrhages, or extravasation of any kind can be discovered. The same symptoms, and the same extent, are not found, though the lesion is removed, and injury of all its organs, but has only been violently shaken; nay, when only the basis of convulsion has seemed to have attended the whole patient." And he afterwards remarks, that "the symptoms attending cerebral disease generally in proportion to the extent of violence which the brain itself has sustained, and which, indeed, is explained only by the symptoms. If the convulsion be very great, all power and power of motion are immediately abolished, and death follows soon; but between this degree and that slight convulsion by which the brain is called which attends most fatal disease, there are many stages." But besides the foregoing description of convulsions, which seems to be that is common to a lesion of function, there is another description, the Asphyctic Cooper has found the many, much degrees of it attended with symptoms of the brain, and slight extravasation. (*Lectures*, p. 322.) The latter, however, are rather to be considered as symptoms rather than as evidence of the disease.

Mr. Brodie has observed that the symptoms of convulsions do not depend upon any kind of disturbance of the organization of the brain as evidence of being diseased, or as by dissection; yet he makes the inference but justified, that there is really no organic change. It is difficult, he says, to conceive in what other manner convulsions of the brain can arise so as to produce the effects which it is known to produce; and it is on consideration that the structure of the brain is so so minute and delicate, and so very susceptible of directing it, it is evident that there may be changes and alterations of structure which are imperceptible of dissection. (*Lectures*, vol. 14, p. 327.)

Mr. Abernethy, I think, has treated in a good deal of the propriety of the symptoms by dividing convulsions into two stages. In fact, without describing them, the various symptoms of the apoplexy, as given by different writers, cannot be as well received.

The first is that state of insensibility and decomposition of the body which immediately succeeds the apoplexy. While it lasts the patient scarcely feels any injury that may be inflicted on him. His breathing is difficult, but is given without exertion. His limbs are relaxed, and his extremities are cold. His mind is quite vacant, but a good deal probably, under the influence of motion, which is applied to the second stage of convulsions. In this, the patient is insensible to pain, and though not regularly performed, are said to be in motion. It is an affluence of the surface of the surface of the body. The body of the patient is not to be disturbed, except in a

state if he is to be disturbed; but he is insensible and insensible to slight external impressions. As the effects of convulsions diminish, he becomes capable of replying to questions put to him in a kind tone of voice, especially when they refer to his state and feelings of the time, as pain in the head, &c.; otherwise he answers incoherently, and as if his attention was diverted by something else. As long as the patient remains in this state of the brain, it is to be maintained; but as the effects diminish, the latter periods tend to increase, and thus continue the third stage, which is the most important of the series of effects proceeding from convulsions.

These several stages vary considerably in their degree and duration; but each or some of each will be found to take place in every instance where the brain has been violently shaken. Whether the last or certain symptoms, or each other or not, I do not know, indeed, they will depend upon a variety of circumstances in the constitution, the injury, and the after treatment; though most to be observed in the latter.

With regard to the treatment of convulsions, a well known fact in the first stage very clearly is, that the patient, when lying in bed, has been in motion, as the brain and nerves are probably, somewhat very suggesting that can be supposed. From a case, and I think, differences existing between the treatment in the first and that which exists in the second, the most powerful stimulus, such as wine, brandy, and volatile alkali, are commonly administered in, as to the patient can be not to swallow. The same may be said, which led to my explanation of these convulsions in the first stage, in order to reveal the identity, as given a kind of convulsion in the position of the body, with a view to control and the brain.

That the patient convulsions were first seen and less favorable. The symptoms of the brain have as far recovered as possible as to rest of the head functions in a degree sufficient to maintain the body in a state of equilibrium, which probably had been partly already weakened by the violent shaking of the day.

And it seems probable that these convulsions were not attended with inflammation, which may have arisen either state. (*Lectures*, vol. 14, p. 327.)

In most cases of convulsions, the patient remains in the apoplexy. According to Mr. Brodie, however, and according to generally early symptoms, and when recovery after the patient has recovered from the first shock of the convulsion. (*Med. Chir. Trans.*, vol. 14, p. 322.) In the beginning, a larger extent is the most general, and considerable difficulty in passing, as mentioned; but afterward the face is sometimes incoherently discolored, and the head becomes attended, seems to require the culture, but after a time the brain also comes away incoherently. There is sometimes blotting at the nose, and a part of the head which drops like the blood is removed by. The pupils of the eyes are partially dilated, but change, and are a little dilated, or sometimes only one. The state of the pupils, however, is differently regulated by different writers, and yet expansion has been found. It is subject to much variety. In that state in which the sensibility of the patient is impaired, but not annihilated, the pupils contract on exposure to light, and are sometimes more contracted than under ordinary circumstances. (*Lectures*, vol. 14, p. 328.) According to Mr. Abernethy, the pupils, although contracted when the patient is insensible, scarcely ever relax if it is disturbed by any effort made by the patient, and the pupils sometimes, probably with great force, in the latter symptoms is generally not relaxed, and is not less hours. The state of the pupils is very different, according to the stage of the disease. It is sometimes the pupils is at first dilated, sometimes contracted, and sometimes incoherently, and the pupils is a very little approaching that of the pupils. Each case is very different, and several cases after the pupils. With convulsions, however, that the pupils of the head is observed by Mr. Brodie to that the pupils of the pupils of the head. In general, when the pupils are not relaxed, and the pupils are in the state which has been described, a kind of the convulsions system takes place, and the pupils are with greater strength in proportion to the state of it was greater in the first instance. The pupils of the head has been unusually severe, there is a kind

above and below the wounded part; and when the parts are examined a short time after the hemorrhage has completely stopped, we find a strain of coagulated blood between the artery and the flesh, extending from a few inches below the wounded part to two or three inches above it, and somewhat thicker in some places than in the wounded part than elsewhere.

Hence, something that the hemorrhage is stopped by a coagulum, it is more correct to say, that it is stopped by a thick layer of coagulated blood, which, during the period that the wounded part is perfectly continuous with the coagulated blood lying between the artery and its sheath.—(Jones, p. 113.)

When an artery is incised, the immediate hemorrhage, by filling the lost space between the artery and its sheath with blood, and consequently distending the sheath, alters the relative situation of the puncture, so the sheath to that in the artery, so that they are not exactly opposite to each other; and by this means a layer of blood is excluded by the sheath over the puncture in the artery, and by compressing them prevents any further effusion of blood.

And this coagulated blood, like the external coagulum of a small artery, affords only a temporary barrier to the hemorrhage; its permanent compression is effected by a process of reparation or of absorption.

Dr. Jones's experiments prove, that an artery, if wounded only to a moderate extent, is capable of re-vascularizing and healing so completely, that after a certain time the hemorrhage cannot be discovered, either on its internal or external surface; and that even oblique and transverse wounds (which give most), when they do not open the artery to a greater extent than one-fifth of its circumference, are so filled up and healed by an effusion of coagulated lymph from their internal lips, as to become, in little or no distinction to the rest of the artery. The transient magnitude of a wound, which will still allow the continuity of the canal to be preserved, is difficult to be learned; for when the vessel is large, but yet capable of being sealed, such a quantity of coagulating lymph is poured out, that the rest of the vessel at the wounded part swells or less filled up by it. And when the wound is still larger, the vessel soon becomes either free or obliterated completely, so that its complete fitness is unimpaired.

Richard made a series of experiments upon dogs, whose arteries he said not to differ much from those of man, though the *superficial* of the heart is not so strong, and the blood is more coagulable; (two circumstances, which should be fully considered in applying any of the information drawn from such experiments to the human subject.) In his first experiment he pricked the femoral artery with a needle; the blood flowed, but soon stopped. On pressing the extremity it again flowed, but in a smaller stream; it gradually ceased to flow, and finally stopped, though the magnitude was again increased. On examination of the artery no trace of the incision was found. Several similar experiments had the same result. In experiment 4, he wounded the femoral artery, and made a longitudinal incision, as it rose from its sheath. The lips of the vessel were open in contact during the distention of the vessels, and to be separated by a jet of water during the rest. The blood was stopped by a coagulum; this was removed twice, and each time the vessel flowed in a diminished stream; but the animal died. In experiment 6, he made the same incision, but did not detach the sheath from the artery, and the wound was left to nature. The hemorrhage was the great; there was an extrusion of blood from the sheath, the size of an almond, which at the end of some days began to drain out, and disappeared in two or three weeks. On the fifth day he examined, fifteen days afterward, a little white ridge was found extending freely in the artery and to the sheath, and extending along the wound. In the interior, there was a deepened longitudinal curvature of the sheath of the fifth of a line. The canal was regular and pervious through its whole extent.

In experiments 7, 8, 9, he made transverse incisions of 1, 2, and 3 of the circumference of the femoral artery, separated from its sheath; in the arteries died. In experiment 10, he made a transverse incision through 1 of the circumference, without detaching the sheath. The bleeding was stopped by a coagulum, but on the animal revived it again flowed, and the dog died. On the next experiment of the same kind the blood was stopped by a coagulum, and the artery was closed by

nearly the same process as in the last experiment. So completely was the cure at the end of six weeks that the external part of the artery did not show any mark of a wound, and the vessels were secured observable on the internal surface. In his fifth experiment he cut one-half of the circumference (the external sheath) and sealed it by a coagulum similar experiments. In experiment 12, he cut 1 of the circumference; after the incision it was much relaxed the bleeding ceased, and the artery was closed in the same manner that it is when the section is complete.

A thousand experiments he concludes wounds of the arteries of dogs are cured by nature when they are only occasioned by a puncture, or a longitudinal incision, whether the artery be detached or not; but when arising from transverse incisions they are always fatal, if the artery be cut low. If the artery retain its sheath, and the wound be 1 of the circumference, it may be cured by the efforts of nature; but it is always fatal if 1 of it be cut through.—(See Quarterly Journal of Medical Medicine and Surgery, vol. 1, p. 35.) The inferences respecting the curability of a wound extending through 1 of the circumference, and the curability of one that affects only 1 of the circumference of the vessel, I should presume would require further examination, notwithstanding an accidental business produced by the sudden loss of blood in the first instance may have been the means of saving even one of the animals in which Richard made his experiments.

This author thinks it probable that a puncture, or longitudinal incision, in the artery of a man may be cured by nature; but that a transverse incision, however trifling in degree, so the clot become displaced, or, if a coagulum is formed, it will be dissolved and torn.

One fact made up by the same professor is, that when an artery is deprived of its sheath for an extent greater than its distance of an inch, the hemorrhage is mortal. I have not yet had time to look over the original paper; but it appears to me, that it would be desirable to know precisely to what extent arteries the nature is returning, when he is making some of the above inferences. The size and number of such animal, the subject of experiments, should also be particularly specified; as experiments made on the femoral artery of a large dog would surely not have the same results as those performed on the same artery of a large fox, weasel, or New Zealand dog.

According to Dr. Jones, the lymph which fills up the wound of an artery is poured out very freely both from the vessel and the surrounding parts, and it accumulates around the artery, particularly over the wound, where it forms a more distinct tumour. The exposed sensitive parts at the same time inflame and pour out coagulating lymph, with which the whole surface of the wound becomes covered, and which completely encloses the artery from the external wound. This lymph grows dense, and the wound is closed up and healed in the manner.—(See *Journal of Hemorrhage*, p. 113, &c.)

PRINCIPAL MEANS OF STOPPING HEMORRHAGE.

It must be plain to every one who understands the course of the circulation, that pressure, made on that portion of a wounded artery which above the wound towards the heart, must check the effusion of blood. The current of blood in the veins, running in the opposite direction, requires the pressure to be applied to that side of the vessel which is most remote from the heart. However, on account of the freedom, and facility with which the fluids are transmitted through the veins, blood, from the portion of the artery above the point of incision into the lower continuation of the artery, such pressure will often stop it, and not necessarily stop the bleeding, unless the part of the vessel directly below the wound be also compressed or secured. As pressure is the most rational means of stopping hemorrhage, so it is the most effectual; and almost all the plans employed for this purpose, are only modifications of it. The ligature, the ligature, the application of a roller and compression, even cauterization, only become useful in the suppression of hemorrhage, on the principle of pressure; the cautery, cauterization, and styptic, however, have a different mode of operation.

In order to prevent a wounded artery from being of hemorrhage, Dr. Jones wound the vessel to be tied with a silk, over which was laid a sponge of gold in cold water, and pressed on the part with the hand. It had

Withstanding these events, the hemorrhage should continue, he recommends immediately applying fresh lard, wet with vinegar; but he is against the use of corroding astringent applications, or at least of the inflammation which they produce; or only success the employment of the tanning issue. When the hemorrhage ceases these methods, he advises five ligatures to be applied to the middle part of the neck; and then dividing the portion situated between them. "Quod et illis quibus plagues venarum, sunt, sunt sanguinis fundant, apprehensibile: utique et, quod istum est, in quo sunt divergent, intercurrentes, sunt, et in se recipiunt, et coalescent, non perinde habent." —(Lib. 3, cap. 25.) When the ligatures were apprehended, the issue of blood prosperity, and no longer necessary measures were resorted to the bleeding part. Celcius reckoned the actual cure.

Gales also mentions tying the vessels for the purpose of stopping hemorrhages, and there are some traces of the same information in other authors, who lived before him, as Arctagoras and Galien. Probably, however, the ligature was little used at those early periods, as may be inferred from the treatment of hemorrhages, caustics, and other applications, which were advised for stoppage of bleeding, and in which less caution would have been paid, had the use of the ligature been familiarly known. No one can doubt, that if the old surgeons had had many specific cases of severe hemorrhages of the ligature, they would soon have used it after dissections; but so far were they from adapting any remedy, that Albucasis, a long while afterwards, refused to operate at the wrist, lest he should see his patient bleed to death.

Part is considered as the first who regularly engaged in the licit use after annihilation. His method having been attacked, he speedily disavows it in the part of the works entitled *Apologia*, where he takes great care to insure the origin of it to the successors, and cites many of those who have made mention of it. However, he thinks it unnecessary in any paragraph of such consequence, that he ascribes his first adoption of this practice to remembrance of the Bible.

The method by which the accounts played upon confidence by the mortgagee-bankruptcy after the expiration of a week, was the characteristic of the car vessel, and surrounding fleet. The same idea affected by the self-ruined an engine, at ground or lost (broken), which blocked up the opening of the vessel, and hindered the coast from escaping. The separation of the engine, however, which eventually took place in some, occasioned a return of bankruptcy, and produced in the more dangerous, as the bankruptcy was now more difficult than before the casualty had been noticed. Sometimes the structure, being too weak to stand, immediately brought away with it the engine. At the present time, the casualty is never employed as a means of suppressing bankruptcy, as, at best, only two or three very unusual cases, in which either compression or the ligature can be made use of. In Great Britain, the casualty can be said to be entirely abolished; but in France, the best surgical surgeons recognized this employ, it is described thus from the attitude of the vessel.

The hot stuporosa also very generously apportioned to bleeding urine placentas, dipped in boiling turpentine—a residue that has come from even freshly shaved wood.

LESTER KUBIE, M.D., WILLIAM L. KUBIE, M.D.

[illegible]

M. is then 25 from large arteries, continuous case after be gradually made, as when these vessels in the immediately over a bone. Bleedings from the radial and temporal arteries are especially noted as cases of this kind, though from the many instances of failure which I have seen happen where the first of these vessels is concerned, I should be reluctant either to advise or make such an attempt. Compression is sometimes tried, when the radial artery is wounded in the forearm. Here it is obviously tried, as preference to the ligature, because the latter cannot be employed without an opportunity to expose the artery.

When there is a well defined, large artery, the following plan may be tried: a ligature is introduced, as far as extended the flow of blood into the vessel. The edge of the external vessel is next to be incised into a slit. Then a compress, shaped like a thick cone, and which is best formed of a series of compresses, gradually increasing in size, is to be placed with its apex exactly on the situation of the wound in the artery. This graduated compress, as it is termed, is then to be bound on the part with a roller.

In this manner, I once bound a wound of the superficial palmar arch, in a young lady at St. George's Hospital. The external wound was very small, and though the hemorrhage was profuse, I imagined that it might be permanently stopped, if compression could be so made as to keep the internal wound incessantly and firmly covered for the space of a day or two. At first, I tried a compress of lint, bound on the part with a roller; but this proving inefficient, I took some pieces of muslin, from the size of a fingertip to that of a half-crown, and, wrapping them up in linen, put the arterial end accurately over the wound, so as completely to cover it. Then the others were wrapped, and all of them were finally confined with a roller, and the next best as quiet as possible in a sling. They were taken off after three days, and no hemorrhage ensued.

It is to be observed, that the palmar fascia, in this instance, would prevent the compression from operating on the vessel; but the case shows that this artery, when wounded, is capable of healing, if the blood be completely prevented from getting out of the external wound by the proper application of compression. Were the outer wound too large to admit of this plan, it would probably be the same practice to put down, at once, to the artery artery, and put a ligature round it, though, as this would very certainly stop the bleeding from out of the vessel in the hand, pressure on the wound would yet be necessary. I have never seen a vessel wound in making the artery is the kind.

Inside compressing the wounded part of the artery, some surgeons also employ a longitudinal compress over the track of the vessel above the wound, with a view of weakening the flow of blood into it. Whatever good effect it may have in this way, is more than counterbalanced by the difficulty when it must occur to the circulation in the arm. If the graduated compress is properly arranged, an effusion of blood cannot possibly happen, and pressure along the course of the artery need at all extend to the extremity. After missing the blood-vessel, if no blood escape from the artery, the surgeon, however, it is to be his constant duty, whether he is certain that the pressure employed is not so powerful as actually to stop the circulation in the forearm and hand. The aim is to keep strictly in a sling, and, as long as there is no bleeding, to place, then, with great caution to prevent that the arm will do well. In this work, I have given no suggestion and description of an instrument, intended by Pott, for making pressure on the wounded femoral artery, at the level of the femur, without passing upon the whole circumference of the limb and consequently without stopping the circulation. For one, however, would prefer not to press upon large arteries are required, except in the kind of cases in which we have just been advised, or in those in which the wounded vessel can be freely compressed against a bony point. Pressure on the circumference of an artery, as the hand, as the femur, and a firm bandage may arrest; and with greater risk is that of nutrition from the unobstructed course of the limb. When the method is tried, the ligatures should always be left loosely around the limb, ready to be tightened in an instant.

Sometimes the external wound heals, while the opening in the artery remains unobstructed, and a false aneurysm is the consequence.

OF THE LIGATURE.

When hemostasis takes place from a large artery in one of the limbs, where the vessel can be conveniently compressed above the wound in it, a short ligature, judiciously applied, never fails to put an immediate stop to the bleeding.

Before the invention of this instrument, which derives its name from the name of the 17th century surgeon, who first used it, a very delicate one. But ligatures of various kinds could be introduced in the extremities, without placing the patient in the most painful position; and many wounds were made, which, with the aid of this simple operation, would not have been attended with the least danger.

The first instance of the instrument has been claimed by J. (1741) surgeon, and ever since it has been used, wherever the ligature, it was first proposed to the public in a form exceedingly simple, so much so, indeed, that it seems extraordinary that its invention did not happen sooner. A small pad being placed on the principal artery of a limb, a band was applied over it, so as to exactly fit the limb. Then a stick was introduced between the two ends of the band, which was twisted; then the pad was made completely to stop the flow of blood into the lower part of the limb.

Although in the 18th century the use of this instrument was a great improvement, it was not until the middle of the 19th century that its use was generally adopted. It is now the first and most important step in the treatment of a wound of a vessel, J. L. Pott is universally agreed to be the first who brought the instrument to perfection, by combining the twisted band with a screw, so that the pressure produced was applied to the principal artery.

The advantages of the modern form of the instrument are, that its pressure can be regulated with the utmost exactness; that it operates chiefly on the point where the pad is placed, and where the main artery lies; that it does not require the aid of an assistant to keep it tight; that it completely compresses the flow of blood into a limb; that it can be relaxed or tightened in a moment; and that, when there is reason to fear a sudden reversal of hemorrhage, it can be left loosely round the limb, and, in case of need, tightened in an instant. The only, however, is attached to the handle, and so the pressure necessary to stop the flow of blood through the principal artery completely prevents the return of blood through the veins, the application cannot be made very tight without inflicting mortification. It is only of use also in putting a sudden stop to profuse hemorrhages for a time, that is, until the surgeon has got to practice some means, the effect of which is more permanent.

OF THE LIGATURE.

The ancients were very unacquainted with the use of the ligature, and though some of their writers have made mention of the ligature, they do not seem to have known how to make proper use of it, nor to have possessed any other certain means of stopping hemorrhages from wounds. In modern times, it is justly considered that what any great surgeon was indebted, while surgery was so imperfect, there was more than food of the patient's life being threatened their lengthened, by what was attempted. Under these circumstances, it is not surprising that the old practitioners should have taken immense pains to discover a great many topical remedies. The new school, however, is known to be a teacher which is only and less power than these methods, no longer could find to make for specific and permanent hemorrhage.

It may, indeed, be said, as a rule in surgery, that whenever large arteries are wounded, no other application should ever be resorted to, but immediate compression should be resorted to, for immediate compression is the best and most certain of all methods.

In order to qualify the reader to judge of the best mode of applying ligatures to arteries, I shall first explain to him their effect on these vessels, as stated by Dr. Jones.

The position learned from Dr. J. Thomson, of Edinburgh, that a vessel is not to be cut, a ligature is applied around an artery, without including the surrounding parts, the vessel root of the limb is torn through by it; and that this has been originally

incised by Denon. Dr. Thomson even demonstrated to Dr. Jones, on a portion of artery taken from the human subject, that the internal and middle coats are divided by the ligature.—(*Journ.* p. 124.)

Thus did Dr. Jones make some experiments on the arteries of dogs and hares, touching to the constitution, that while several ligatures are applied round an artery with such close application to each other as to interfere with the coats, although the coats be immediately afterward removed, the vessel still remains closed. In proof of the part which was tied, as far as the first collateral branches open and below the obstructed part. Dr. Jones thinks it reasonable to expect that the obstruction produced in the arteries of dogs and hares, in the manner he has related, "might be effected by the same treatment in the arteries of the human subject; and if it should prove successful, it might be employed in cases of the most important cases in surgery. The success of the late important operation in which three arteries were tied in the operation for aneurism, only perhaps equal to most operations he have recorded, and operating sufficiently simple and safe; but if it is possible to produce obstruction in the canal of an artery of the human subject in the above-mentioned manner, may it not be advantageously employed in the case of aneurism; inasmuch as without need to wait to prevent the immediate action of the external vessel?" Dr. Jones asks questions whether this mode of obstructing the passage of blood through the arteries may not be advantageously practised in cases of hemorrhoids!—(*P.* 124.)

Subsequent experiments have not been equally successful with Dr. Jones in obtaining the obliteration of the artery of the vessel after this operation. Did this difficulty depend from their having tied the vessel only in one place? Mr. Hodgson made the experiment in connection upon the external arteries of dogs; and in order of them was the artery of the vessel obliterated. The same experiment has been repeated by several surgeons upon the arteries of dogs and hares, but in no example, as far as Mr. Hodgson knows, has the complete obliteration of the artery of the vessel been accomplished. However, as an effect of ligation is an inevitable consequence of the operation, the want of success is owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion.—(*See Observations on the Application of the Ligature to Arteries, &c.* by R. TRAVERS, vol. 4, Med. Chir. Trans.) The presence of the lymph, in the various coats of its application, effects the object; and for the success of Dr. Jones's experiment, it appears only necessary that the opposite sides of the wounded vessel should be retained in contact until their adhesion is sufficiently consolidated to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure as shall retain the opposite sides of an artery in contact at the bottom of a wound would be too great to permit its employment. It occurred to Mr. TRAVERS, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to ensure the obliteration of the canal; and by the removal of the ligature at this period, the intervention of strapping the artery would be avoided. The danger produced by the constriction of a ligature upon an artery arises from the stricture which, as a foreign body, it produces in its coats. Ligation has never been shown to be necessary in less than twenty-four hours after the application of a ligature; while it is an acknowledged fact that lymph is in a favorable state for organization in less than six hours, in a wound the sides of which are preserved in contact.—(*Journ.* chap. 4, exp. 1.) It is sufficient, therefore, to ensure their adhesion, that the wounded ends of an artery be kept in contact by a ligature only three or four hours, afterwards and allowing only in a great degree to be removed by preventing the immediate admission of the blood. Justified by this reasoning, Mr. TRAVERS performed several experiments, by which he ascertained, that if a ligature be kept six, ten, twelve, or even one hour upon the external artery of a hare, and then removed, the artery is sufficiently adhered to secure the permanent obliteration of the canal. It appeared probable that the same result would be obtained upon the blood-vessels of a human subject.—(*Hodgson on the*

Arteries of Arteries, &c. p. 228, at seq.) Mr. A. G. HASTINGS, in the year 1800, tied the branch of an artery of two dogs, and removed the ligature immediately after their application. In both instances, the complete obliteration of the vessel of the artery was the consequence of the operation.—(*See Practical Observations on Surgery, p. 125.*) He has also tied this vessel, as testified by Mr. TRAVERS, in an operation which is performed for a ruptured aneurism in a vessel, in the thigh. A single ligature was passed under the injured artery. The ligatures were tied with linen or silk-threads, about a quarter of an inch of the vessel being left undisturbed between them? As that time elapsed, the pulsation in the vessel was a slight indistinct motion. Twenty-six hours having elapsed since the application of the ligatures, the vessel was carefully opened, and the ligatures tied and removed, without the slightest disturbance of the vessel. It less than had a minute afterward the artery being dissected with blood, and the pulsation in the artery even as strong as they had been before the operation. Mr. HASTINGS then applied two fresh ligatures, an inch apart, and the patient died.—(*See Practical Observations on Surgery, p. 125, &c.*) Now, as Mr. HASTINGS shows in applying ligatures, we find that the pulsation returned, the above case only proves that the artery was not obliterated in about six hours, and as we are left in the dark respecting the great question, namely, whether the vessel would have become obliterated by the effect of organizing lymph and the adhesive inflammation, notwithstanding the state of resistance through it. As for the hemorrhage which occurred, I think it might have been avoided, consisting the disturbance and irritation which the artery must have sustained in the proceedings, thereby necessary for the application of not less than two ligatures, and also increased in kind of them. Accordingly say above, only one ligature ought to have been used, and time of the artery described. We also learn in connection on the use of ligatures which were employed, the successful issue of ligation in forming a judgment of the merits of the preceding method. The application, removal, and reapplication of ligatures are not consistent with the new principles promulgated by the late Dr. Jones, and have, in every instance, that attended by my friend Mr. HASTINGS, brought in obliteration of the artery and hemorrhage. For further information on the question concerning the power of withdrawing the ligature previously to its withdrawal, see the article *Aneurism*.

From Dr. Jones's experiments, it appears that the first effects of a ligature upon an artery are, a complete division of its internal and middle coats, the tearing of its wounded surfaces into contact with each other, and an obstructions to the circulation of the blood through the canal. There must be a small quantity of stagnant blood just within the extremity of the artery, but this does not, in every instance, immediately form a coagulum capable of filling up the canal of the artery. In most cases, only a slender coagulum is formed at first, which gradually becomes larger by successive coagulations of the blood; and hence the coagulum is always at first of a tapering form, with its base at the extremity of the artery. But as Dr. Jones says, the formation of this coagulum is not material, for soon after the ligature has been applied, the rest of the artery swells, and the wounded internal surface of its coat being kept in close contact by the ligature, adheres and converts this portion of the artery into an important wall, at first, slightly oblong and. It is in the effect lymph that the base of the coagulum adheres, when found to be a vessel. Lymph is also effused behind the coats of the artery, and among the parts approaching its extremity. In a little time, the ligature under the part on which it is directly applied swells, and acting as a tent, a small aperture is formed in the left of lymph effused under the artery. Through this aperture a small quantity of pus is discharged, as long as the ligature remains; and finally, the ligature itself becomes necrotic, and the little cavity which it has occupied gradually and fills up, and the external wound heals, leaving the cellular substance a little beyond the end of the artery again thickened and indurated.—(*Journ.* p. 125, 126.)

In short, when an artery is properly tied, the following are the effects, as enumerated by Dr. Jones:

1. To cut through the internal and middle coats of the artery, and so bring the wounded surface into perfect apposition.

2. To cause a dissemination of blood to the entire arterial branch.

3. To allow the formation of a coagulum around and within the artery, *per se*, and a collateral branch below every point of the ligature. In certain particular cases, however, that being the basis of a collateral branch prevents the formation of the coagulum, a coagulum may prevent the completion of the arterial process. In the experiments made on the arteries of fishes and dogs, by Mr. Brown, the ligature was regularly applied twice to each artery, because, on the second, more easily obtained.—(See *Med. Chir. Trans.* vol. 5, p. 426, 427.)

4. To create infarction in the internal and middle coats of the artery, by having cut them through, and consequently, to give rise to an effusion of lymph, by which the wounded surface is united, and the coagulum is rendered permanent, in position, a coagulum is likewise formed in the surrounding arterial surface of the artery by which it becomes very much thickened with effused lymph; and, at the same time, from the exposure and inevitable wounding of the surrounding parts, an immense infarction is formed, and an effusion of lymph, which converts the artery, and forms the surface of the wound.

5. To produce absorption in the vessels of the artery around which the ligature is immediately applied, and an external one.

6. To produce ultimately a complete obliteration, not only of the vessel of the artery, but even of the artery itself, to the collateral branches on both sides of the part which has been tied.

7. To give rise to an enlargement of the collateral branches.—(See *Journal*, 1823, 1834.)

Every part of an artery is organized in a singular manner to its other soft parts, and its coats are susceptible of the same process of absorption, increase, &c., as the other parts are. Hence, the preparations taken to secure the effect of other parts should be observed for the same purpose with regard to an artery. The blood is put in a state to admit of adhesion by the ligature, which, when properly applied, cuts through the internal and middle coats, keeps these cut surfaces in contact, and affords them an opportunity of uniting by the adhesion of albumen, as other cut surfaces do. The immediate stoppage of the blood in arteries the ligature and temporary part of what the ligature has to accomplish, it has also to effect the adhesion of the internal and middle coats of the artery, which, being the state on which the permanent suppression of hemorrhage depends, is the most important. The state of the artery, whether completely tied, or compressed, have no effect, as Dr. Jones remarks, sufficiently attended to; nor is the degree of force employed in tying the artery after considered. Some surgeons, wishing to guard against the ligature slipping off, tie it with very considerable force; while others, apprehensive of cutting through the artery, or of decomposing too early a separation of the ligature, draw it only sufficiently tight just to prevent the escape of blood. A broad flat ligature is not likely to make such a wound in the internal and middle coats of the artery as is more favorable to adhesion, because it is scarcely possible to do it in a manner round the vessel, which is very likely to be struck, cut aside, or ruptured by it, and consequently to have an irregular, broken wound made in its middle and internal coats. By applying also a considerable strain of the external coat, it may destroy the very vessels which join it in their way to the cut surface of the lower coats, and thus render them incapable of flowing. Thus opposing the speed to flow, and with a ligature that covers that part of the external coat which is directly over the newly united part, and, consequently, as soon as it has produced absorption through the external coat, it will have the same effect on the newly united parts, and, of course, secondary hemorrhage.—(See *Journal*, p. 185.)

When a incision is to be made in an artery, it is apt to cut through the internal and middle coats of an artery more completely at some parts than others; but these parts may be perfectly cut through, in order to produce an effusion of lymph from the inside of the vessel, which seems to affect most early at its cut surface.

Also, when the ligature is not applied with sufficient tightness, the inner coats of the artery will not be properly cut through. Dr. Jones thinks that the ligature, being sometimes put on so as to divide from a circle, has a tendency to produce secondary hemorrhage.

Dr. Jones observes that ligatures are less, when they are intended and apply them; and he adds, that though they are slightly necessary to cut through the internal and middle coats of an artery, it is better to be the vessel more easily than to necessarily destroy it cut through its inner coats, because the cut surface will then be more easily kept in contact; the separation of the ligature impeded; and the danger of absorption spreading to the healthy surrounding parts diminished. The material part will never absorb through more than its long ends have adhered. The link, however, should be kept in a perfectly quiet state.

I am sincerely glad to find that no moderate an obstruction as Dr. Jones has referred the idea that ligatures occasionally slip off the vessels, in consequence of the violent action of the blood. In fact, the blood does not continue to be applied against the extremity of the artery, with the same impetuosity with which it is expelled through the vessel before it was tied. The blood is immediately converted into the collateral branches, and is there any pressure for some way above the ligature.

Dr. Jones, indeed, more rationally imagines this accidental accident arises from the constriction of the artery, which prevents the lymph entering and covering round the artery, or to the last having been applied with sufficient tightness, or to its having that very minute hole of the vessel which the deviation from the circular application would produce.—(P. 123.)

Dr. Jones is of opinion, that in cases of aneurism, in which the artery has only been tied with one ligature, and left undisturbed, and in which secondary hemorrhage has arisen, that this has most probably been arising either from the changed state of the artery; or to some extraneous far from passing a large portion of the vessel; or to some loose ligature about the end which is tied; or, lastly, or not tying the artery sufficiently tight to cut through the internal and middle coats, so as to fit them for adhesion. The latter supposition, hardly has to produce a gradual absorption of these coats, and to cause bring on hemorrhage, which returns with greater violence as the absorption advances.—(P. 125.)

These remarks must also strongly explain why Scarpa's practice of using a large ligature, with the intervention of a piece of cloth between the cord and the vessel, for the express purpose of kindling the outer coats of the vessel from being divided, must be objectionable, because it may burst down as an aneurism in all positions where large arteries are to be tied, and particularly of such as are in contact with the artery, should be diminished as much as possible. And though it may be disposed to go so far with Scarpa as to believe that the introduction of a piece of cork or wood is more than that of a cylinder of linen, I cannot assent to the proposition that the latter is free from objection, because it gives rise to a cushion, than as a body likely to burst.—(See *Mem. on the Ligature of Aneurism*, p. 45.)

With the difference in the constitutions of men and animals, I know that the results of experiments on the latter can never be looked upon as a positive proof of what would happen from the same experiments performed on the human subject. The stronger or weaker impulse of the heart, the more or less sanguine state of the blood, the greater or less degree of general and local anæmia, the state or loss of quick tendency to adhesion, inflammation and absorption, are circumstances which must make in different manner the same experiments lead to opposite results. The question whether a small round ligature, or a larger flat one, with a piece of linen between it and the vessel, be best, must therefore, after all, be decided, not by Dr. Jones's experiments, nor those of Scarpa, or Elliot, but by the practice of surgery on the human body; and that the principles defended in this Dictionary are, on the whole, to be preferred, can hardly be questioned by any man who knows how much less frequent secondary hemorrhages now is in this metropolis than it was formerly, when those principles were justly observed and comprehended.—(See *Anatomical, Anatomical, Anatomical, and Ligature*.)

Dr. Jones seems to consider, that the advantage of the retraction of the divided artery within the vascular sheath is compensated, in the case of the divided artery, by the speedy and profuse effusion of lymph, which takes place over and round the vessel at the distal part, and soon covers the ligature itself. Another cause of secondary hemorrhage is, the loosening of other parts in the ligature, together with the artery; by means of which the division of the inner coats of the vessel may be prevented.

In the valuable publication of Dr. Jones in which I have so freely availed, some secondary hemorrhages are also assigned to the laceration or separation of the recently united parts of an artery, by pressure and extraordinary exertions of the patient. Hence, his strongly is now on keeping a limb in which a large artery has been tied perfectly at rest.

I shall conclude these remarks on the ligature with a few practical rules.

1. Always tie a large artery as separately as possible, but still let the ligature be applied to a part of the vessel which is close to its natural constriction.

Results the persons for this practice already specified, we may suppose, that including other substances in the ligature causes increased pain, and a larger part of a vessel to remain divided. The ligature is also apt to become loose, as soon as the adhesion between it and the artery sloughs or dissolves. Sometimes the ligature, thus applied, forms a circular groove in the flesh, and remains a tedious raw, susceptible of a separation.

The blood-vessels being organized like other living parts, the breaking of a vessel and artery can only take place favourably when that part of the vessel which is immediately contiguous to the ligature continues to receive a due supply of blood through its own vessels, which are ramifications of the collateral arteries. Hence the disadvantages of putting a ligature round the middle of a portion of an artery, which has been separated from its surrounding connections; and hence the utility of making the knot as close as possible to that part of the vessel which has retracted against the surrounding flesh.

Small arteries neither allow nor require those minute attentions to the mode of tying them.

2. When a divided artery is large, open-mouthed, and quite visible, it is best to make hold of it, and raise its extremity a little way above the surface of the wound with a pair of forceps. When the vessel is smaller, the hemorrhage is the most convenient assistant.

3. While the surgeon holds the vessel in this way, the assistant is to place the nose of the ligature under it, and to it, according to the above directions. In order that the nose may get fine and high, and even above the mouth of the artery, when it is tightened, the ends of the ligature must be drawn as far apart as possible, which is best done with the thumb. A knot is next to be made.

4. As ligatures always separate in wounds as extraneous bodies, and are half of such a sufficient for the removal of the wound when drawn, the other should be cut off close to the knot, and taken away.

As we have explained in the article of Application, and as we shall before again in speaking of the Ligature, these have of long years been under the pressure of cutting off both ends of the ligature close to the knot, with a view of diminishing, as far as possible, the quantity of extraneous substance in the wound. This plan requires the use of very small silk ligatures, in order to be fully justified of.—See Mr. Lawrence's *On the Ligature*. Paris, vol. 6, p. 143, of sec. 1.

5. When a three-artery is completely divided, two ligatures are to be tied, the other on the lower part of the artery is not so necessary, it is recommended by the experienced surgeons employing the knot very readily into the part of the artery most remote from the knot, as soon as the first ligature has been applied.

6. When a large artery is only punctured, and no pressure must be put on it, the vessel is to be first exposed by an incision, and then a double ligature introduced, made it, with the aid of an eye-pick. One ligature is to be tied above, the other below the bleeding orifice, with the arteries in the position explained in this article, and then cut and buried.

7. Ligatures usually cover away from the wound artery over and, in case of a hemorrhage, and from those of moderate size in six or seven days. When they col-

lapse attached much beyond the point period, it is proper to draw them very gently every time the wound is dressed, for the purpose of accelerating their detachment. Great care, however, as to the mode of doing this, as Mr. Jones remarks, as long as the ligature seems firmly attached, placing a moist sponge, moist with water or alcohol the recently separated extremity of the artery, which is not only necessary in it, but is not wanted in that period of the artery (the external coat) which remains the ligature.—(See p. 115.)

In particular individuals there appears to be an extraordinary tendency to hemorrhage from very slight injuries. An instance of this kind has been recorded by Mr. Hughes, where a small hemorrhage arose from the extraction of a tooth. The patient, who was twenty-seven years of age, had lost a tooth without a loss, in consequence of which operation the bleeding continued for twenty-one days from the socket before it ceased. A very slight cut on the hand was also followed by an alarming hemorrhage, which could not be stopped by pressure, or pressure, or the ligature, so that it became necessary to apply the last process, which succeeded. He has since another career with this sort, a profuse bleeding followed, which issued in effect of dyspepsia, emaciation, and every kind of ailment as the result. The actual cause was not ascertained. The danger of this kind of hemorrhage is to leave no other resource, but that of tying the vessel, which was done by Mr. Hughes. He says the proceeding failed to suppress the hemorrhage, which proved fatal.—(See Med. Lib. Trans. vol. 4, p. 12, Lond. 1815.) In the mode of stopping hemorrhage from the sockets of the teeth, the reader may find some remarks in the *Edin. Med. and Surg. Journ.* Vol. 1, p. 161.

The hemorrhage from the bites of insects sometimes proves exceedingly abundant, and sometimes of long duration, these have occasionally happened, particularly in children. When common methods fail, it has been best, perfectly tried of passing a fine sewing needle through the skin on one side of the wound and then another through the skin on the opposite side, and then twisting some thread round the needles, so as to draw them together, and close the bite. The experiment fully answered.—(See *Edin. Med. Repository*, Vol. 1, p. 21, 1815.)

For more information respecting hemorrhages, see *Amputation*, *Amputation*, *Arteries*, *Arteries*, and *Wounds*.

Consult also *Pott's Memoirs*, among them *of Treat. des Arteries* for the years 1770, 1772, 1773, 1774, 1775, 1776, 1777, 1778, 1779, 1780, 1781, 1782, 1783, 1784, 1785, 1786, 1787, 1788, 1789, 1790, 3078, 3079, 3080, 3081, 3082, 3083, 3084, 3085, 3086, 3087, 3088, 3089, 3090, 3091, 3092, 3093, 3094, 3095, 3096, 3097, 3098, 3099, 3100, 3101, 3102, 3103, 3104, 3105, 3106, 3107, 3108, 3109, 3110, 3111, 3112, 3113, 3114, 3115, 3116, 3117, 3118, 3119, 3120, 3121, 3122, 3123, 3124, 3125, 3126, 3127, 3128, 3129, 3130, 3131, 3132, 3133, 3134, 3135, 3136, 3137, 3138, 3139, 3140, 3141, 3142, 3143, 3144, 3145, 3146, 3147, 3148, 3149, 3150, 3151, 3152, 3153, 3154, 3155, 3156, 3157, 3158, 3159, 3160, 3161, 3162, 3163, 3164, 3165, 3166, 3167, 3168, 3169, 3170, 3171, 3172, 3173, 3174, 3175, 3176, 3177, 3178, 3179, 3180, 3181, 3182, 3183, 3184, 3185, 3186, 3187, 3188, 3189, 3190, 3191, 3192, 3193, 3194, 3195, 3196, 3197, 3198, 3199, 3200, 3201, 3202, 3203, 3204, 3205, 3206, 3207, 3208, 3209, 3210, 3211, 3212, 3213, 3214, 3215, 3216, 3217, 3218, 3219, 3220, 3221, 3222, 3223, 3224, 3225, 3226, 3227, 3228, 3229, 3230, 3231, 3232, 3233, 3234, 3235, 3236, 3237, 3238, 3239, 3240, 3241, 3242, 3243, 3244, 3245, 3246, 3247, 3248, 3249, 3250, 3251, 3252, 3253, 3254, 3255, 3256, 3257, 3258, 3259, 3260, 3261, 3262, 3263, 3264, 3265, 3266, 3267, 3268, 3269, 3270, 3271, 3272, 3273, 3274, 3275, 3276, 3277, 3278, 3279, 3280, 3281, 3282, 3283, 3284, 3285, 3286, 3287, 3288, 3289, 3290, 3291, 3292, 3293, 3294, 3295, 3296, 3297, 3298, 3299, 3300, 3301, 3302, 3303, 3304, 3305, 3306, 3307, 3308, 3309, 3310, 3311, 3312, 3313, 3314, 3315, 3316, 3317, 3318, 3319, 3320, 3321, 3322, 3323, 3324, 3325, 3326, 3327, 3328, 3329, 3330, 3331, 3332, 3333, 3334, 3335, 3336, 3337, 3338, 3339, 3340, 3341, 3342, 3343, 3344, 3345, 3346, 3347, 3348, 3349, 3350, 3351, 3352, 3353, 3354, 3355, 3356, 3357, 3358, 3359, 3360, 3361, 3362, 3363, 3364, 3365, 3366, 3367, 3368, 3369, 3370, 3371, 3372, 3373, 3374, 3375, 3376, 3377, 3378, 3379, 3380, 3381, 3382, 3383, 3384, 3385, 3386, 3387, 3388, 3389, 3390, 3391, 3392, 3393, 3394, 3395, 3396, 3397, 3398, 3399, 3400, 3401, 3402, 3403, 3404, 3405, 3406, 3407, 3408, 3409, 3410, 3411, 3412, 3413, 3414, 3415, 3416, 3417, 3418, 3419, 3420, 3421, 3422, 3423, 3424, 3425, 3426, 3427, 3428, 3429, 3430, 3431, 3432, 3433, 3434, 3435, 3436, 3437, 3438, 3439, 3440, 3441, 3442, 3443, 3444, 3445, 3446, 3447, 3448, 3449,

Journal, Vol. Paris, 1855. John Grant, A Case of Anomalous, with some Experiments and Observations on the structure of Arteries with minute fine Ligatures, in *Lond. Med. Repository*, vol. 7, p. 334. "The author relates several experiments for the purpose of ascertaining the ability of living arteries with such ligatures, and within the few weeks of time to the end. They were performed on the carotids of dogs and cats. The conclusions are unfavorable to the practice. After one case of amputation, where the patient was tried, the artery healed slowly, and for several months small aneurysms repeatedly formed."

HEMORRHOIDS. (From *haima*, blood, and *rhoe*, to flow.) Piles, divided into such as do not bleed, and termed blind, and into others which in occasional hemorrhages, and distinguished by the epithet of anal. The etiological sequence of the disease is evidently only a discharge of blood. Scrophulous, however, sustained by long violence, have generally supplied by the term hemorrhoids either a simple bleeding from the veins of the lower part of the rectum, remaining many or less frequently, yet not accompanied with any discolourable permanent tumour within, or on the outside of the anus; or else aneurysms formed by a various distension and morbid thickening of those vessels, either with or without occasional hemorrhage; or lastly, tumours slightly produced by effused blood, but subsequently converted into an organized substance.—(Abernethy, *Surgical Works*, vol. 3, p. 324.)

According to Richter, blind hemorrhoids consist of preternatural cysts or sacs at the lower extremity of the rectum, from the size of a pea to that of an apple. Sometimes they are distended with blood, and very much swollen, and another period entirely subsides; though, when they have been often considerably swollen, they never quite disappear, but are alternately, in a full enlarged state suddenly and tacitly. Indeed, the more frequent and considerable the enlargement has been, the greater is the risk. It is generally supposed, that these tumours or cysts are various expansions of the veins of the rectum; and probably, says Richter, this may sometimes really be the case; but the disease is not always of this nature. In particular instances, and, perhaps, in most cases, they arise from an extravasation of blood under the inner coat of the rectum; and then the cyst is altogether formed by this excretion, and not by distension. The following circumstances furnish proof of what has been here observed. Hemorrhoids are sometimes as large as a walnut or apple; yet it is scarcely credible, that a mere tumour could sustain such a strain. When set away, the bleeding is often very slight, even when they are large. Surely, if the tumours were various, there would always be profuse hemorrhage. Sometimes the cyst is found quite empty; but how can a cyst be supposed to be in that state? The shape of hemorrhoids is also remarked to be subject to greater variety than can hardly admit of doubt; of which, that they are sometimes oblong, sometimes cylindrical, like a finger, &c. Lastly, when set away, the size is usually seen to assume only of a single magnitude.—(Abernethy, *de Vaginitis*, A. 6, p. 28, ed. 2, Gall. 1803.)

At the same time, it should be collected that in the bloodlessness consequent on the effused vein, and the swelling becomes hard, indurated, and very painful. The collection is subsequently absorbed, but the thickened coats of the vein and the surrounding parts form a tumour which is liable to inflame and shed great disease.—(Hoffman in *Journal of Medicine*, A. 6, p. 265.) In short, all surgeons who consider the disease as various, plead, with Sir E. Home, that in cases of long standing, the contents of hemorrhoidal tumours "coagulate and become solid; these cysts increase in thickness, and they remaining persistent expose to various other situations in the body."—(De Boer, &c.) Avoiding, however, of the extensive opportunity afforded by his directing point, Mr. Keay has taken some pains to ascertain the nature of these tumours; and he observes, "I confess you say, that they seemed to be formed of a various distension of the great hemorrhoidal vein, even in a single instance. In every case of extreme hemorrhoids, the cancer appeared to be composed of a preternatural of the rectal substance in a state of unusual firmness, supported by some vein, and covered by the integuments. The veins were branches of the internal iliac. In every case of internal hemorrhoids, the structure was pretty similar. The veins, however,

were enlarged, and were branches of the hemorrhoidal."—(On certain severe Forms of Hemorrhoidal Excrescence, p. 40.)

The opinion that piles are formed of cells filled with blood is also adopted by Mr. Keay. The structure of the hemorrhoidal veins with blood, he observes, gives rise to tumours; but if any of their blood is extravasated in the cellular membrane, in the interior and internal part of the mass, hemorrhoids are the result. If the cellular membrane, void of democracy in hemorrhoidal patients, the transference of the vessel are with tenderness in these cysts of blood, and are completely removing the whole, the hemorrhoids appear suspended from the branches of the vein, as grapes from the vine.—(See *Keay Med. & J. Soc.* 1825.) Whistler, well known as the author of a famous treatise on the present subject, is the only writer who defines a hemorrhoid to be a preternatural distension of blood (phlegm, sanguis) to the extremity of the rectum, because he conceives that hemorrhoids, scrophulous, &c. are scrophulous circumstances, not constantly attending the disease.—(See *Med. des Sciences* A. 6, p. 445.)

Whether the contents of some piles being formed of distinct cysts, or mass of blood be correct or not, there is no doubt, that the tumours sometimes consist of a various enlargement of the branches of the hemorrhoidal vein. Were this not the fact, how could cases like the following ever take place? "One of my patients (says M. Delamar) had several of these tumours of very large size, and at every contraction of the sphincter and the blood issued from them, as water."—(Med. Phil. vol. 211.) Monteggia has likewise seen two instances in which the blood issued out of the tumours in a continued stream.—(Med. des Sciences A. 6, p. 452.) And Richardson mentions a physician who lived to the age of eighty-two, quite free from infirmity, and whose good health was ascribed to periodical bleedings from piles, during his years of his life; the evacuation being very regular, and so profuse, that the blood was always some distance, as from a vein opened in phlebotomy.—(See *Boerhaave*, Chir.) If such piles were not either tumours, or cysts in direct communication with the large veins of the rectum, it is would not have succeeded in taking blood from them by pressure, as he often did in the case of the ordinary mode of venesection.—(Med. Chir. T. 2, p. 131.)

Hemorrhoids may, in number, size, form, and situation, some being external; others internal; and some hardly larger than a pea, while others exceed a hen's egg in size. Sometimes they bring on very serious complaints, either by harassing and discharging blood copiously and dangerously to exhaust the patient; or by exciting inflammation of the adjacent parts, and causing abscesses and fistula; or, lastly, by becoming strangulated by the contraction of the sphincter ani, so as to occasion severe pain. Piles which bleed but little are not of much consequence; but those which bleed profusely cause violent pain, or which induce inflammation and all its effects, demand the greatest attention. External tumours of a person who lost three quarters of blood from some piles at the centre of a couple of days; and both Arnes and the celebrated pathologist Cullen are said to have died so death as the matter.

I do not know what remedy ought to be given to the hemorrhoids caused by Puzos, in which a Spanish soldiering walked every day, six feet, a pint of blood from some hemorrhoids, and yet enjoyed perfect health.—(See *Chir. Journal*, 2, p. 46.) For other curious facts of this nature, see *Med. des Sciences* A. 6, p. 452.

As Mr. Rowland remarks, hemorrhoidal tumours, when combined with inflammation, are very painful. "The patient can then neither walk, ride, nor sit; the only tolerable state being that of rest in the recumbent position. Should fail, during the continuance of inflammation, be obliged to place a tumour, the distress is extreme. With these symptoms there is generally, more or less feverish heat and tenderness, more and more distress."—(On Diseases of the Lower Intestines, p. 325, ed. 5.)

In passing, when piles are situated far up the rectum, they are less painful than when lower down, and sometimes the patient is not conscious of having them till he begins to void blood from the rectum. In the former case, the veins of tumours are surrounded by soft and yielding substances, which do not make

any painful pressure on them; but when they are situated towards the anus, they often suffer painful compression from the action of the sphincter muscle. Mr. Horsburgh met with two examples where hemorrhoidal swellings were situated with inflammation, and so violently strangled by the spasmodic action of the sphincter, that the parts underwent a spontaneous identification, and a radical cure was the result.—(*J. Transactions of the Medical Association, vol. 2, 1843, p. 23*.)

With regard to the *relief of hemorrhoids*, any thing capable of extending the action of blood through the hemorrhoidal veins may be considered the disease. The pressure of the gravel *lithis*, catarrhs, and the frequent retention of hardened feces in the rectum, are very frequent causes. Persons who lead sedentary lives are often troubled with the complaint. Women are even attacked in child birth.

The removal of the enlarged liver, or of water accumulations in the cavity of the peritoneum, may occasion relief.

I have adverted to the opinion of Meisner, that hemorrhoids depend upon a determination of blood to the lower part of the rectum; which supposition is perhaps correct in cases where the disease assumes hemorrhoidal in that form, in the neighboring parts.

When the tumors are produced by the pressure of the great artery, no cure can be expected (if the delivery, when once passed, follows spontaneously). Alas! when piles are an effect of disease, they cannot get well before the pressure of the fluid in the abdomen has been removed by bleeding. Gentle laxative medicine and a protracted position of the body tend to alleviate the pain, and induce the evacuation of feces. Through the action of an external compress of equal parts of the powder of oak-bark and of sugar of lime, or high fluid compresses to the same beneficial effect. The application of warm water by means of a bath, or enema, or local vesicatory produces relief in great cases. When piles are constituted by the sphincter too spastic, the pain may often be at once removed by pushing the swelling up the rectum, and using emollients or even the warm bath. Mr. Horsburgh, in cases where the disposition to spasm in the sphincter is associated with high irritability in the bowels, recommending the introduction of a metallic bougie for a certain length of time, the size of the instrument and frequency of repetition of the operation being daily regulated.—(*On Diseases of the Lower Intestines, &c. p. 154, et. 2.*) When the disease is in a state of inflammation, leeches applied to the vicinity of the sides, and puncturing the dilated hemorrhoidal vessels with a lancet, for the purpose of taking away blood, and the application of cold lotions, are measures occasionally employed to procure cure. The treatment of leeches was particularly recommended by Deschamps.—(*De Morbis Recti, Schreyer, 8. 1, p. 167.*) Petit preferred the latter.

According to Mr. Horsburgh, when there is "discharge of hemorrhoids from the veins within the sphincter, with perhaps little or no external tumour, one of the best means of relief is the rectal bougie, regulated by the patient's feelings, and also by the protraction with which inflammation and consolidation take place."—(*On Diseases of the Lower Intestines, &c. p. 215, et. 3.*)

When the number and size of hemorrhoids are so considerable, as materially to obstruct the discharges of the bowels, when they are severely painful, and subject to profuse bleedings, when the patient is disabled from following his usual occupations, and when the above means afford insufficient relief, the surgeon should recommend their removal.

The excision of piles with the actual cautery and cauterium, as practised by the old surgeons, is now altogether relinquished. The only case ever followed in the present state of surgery is, either to cut the framework of a pair of hemorrhoids or knots, or to apply a tight ligature round their base, so as to cause them to slough away. If possible, the opportunity of doing either of these operations should always be taken when the disease is in a scabrous state.

When piles are to be cut off, and they are not sufficiently spastic, the patient must first strain, as it were, in order to make the remaining mass apparent. With the aid of a pair of dressing forceps, the skin covering the hemorrhoids is then to be separated from them with the knife, but not cut away, and the tumour is then held off with a vaseline, and is to be removed.

Solinger states, that cutting the skin is very essential, for any hemorrhoids which may arise, will then be more easily suppressed; and when there are several hemorrhoids, so to excise them, the loss of resistance about the anus will be less, and, of course, the blood will not be so liable to a correction of this sort, which is sometimes a very great affliction.

Previously to the performance of any operation, Mr. Abernethy endeavours to bring the patient into a more regular state, and takes care to clear them with any medicine found by experience to answer the purpose without inducing a continuance of irritation and swelling. "The bowel being cleared in this manner, no efforts need be exerted in evacuating the bowels, and the pain relieved by bathing with tepid water, the pain should be taken hold of with a double knot and removed with a pair of scissors. A protruded and hardened pile at the bowel may be removed in the same way; but I think it is best to make the history of the hemorrhoid the depth to which the action may extend is necessary. The venous mass by the knife resembling this, could then be joined at each extremity." The direction of the incision, both for the removal of piles, and that of the place, he says, should be longitudinal in the direction of the bowels. When there is a transverse fold of the lowest of considerable extent, he prefers taking away two elliptical portions in the long axis of the tumor.—(*See Abernethy's Surgical Works, vol. 3, p. 209.*)

As I have expressed in the former part of the work (*see Essay, Postscript, &c.*), Mr. Abernethy and I removed these extensive diseased folds about the time of the late, with great success. A. L. Petit followed the same practice (*Mal. Char. 2. 2, p. 134*) and more recently Mr. Kirby.—(*On the Hemorrhoidal Excision, Lond. 1817.*)

The late Mr. Ware published some remarks, the object of which is to prove, that when there are several hemorrhoids, the removal of one or two of the most painful of them, with a pair of scissors, will afford immediate relief.

The excision of piles is occasionally followed by dangerous bleeding, as is exemplified in a case related by Petit. A patient had some hemorrhoids, which were supposed to be external, while they were just beginning to protrude. Almost immediately after they had been cut off, the skin which had supported them was drawn towards the anus. An internal hemorrhage ensued, which could not be suppressed, and proved fatal in less than five hours. The rectum had come away, and all of blood, coagulated blood. Sir E. Home speaks of some instances within his knowledge, where, after the removal of internal piles with the knife, the bleeding continued till.—(*On Ulcers, p. 363.*)

If the bleeding should be troublesome, and proceed from vessels within the rectum, the best plan would be to distend the gut with a suitable piece of sponge, so as to make pressure on the wound. Cold should also be applied to the rectum and tail.

The removal of hemorrhoids with a ligature can generally be done with sufficient safety; but still when hemorrhoids, though they are not constant, are frequently protruded this method without any doubts, in other instances, he had reason to regret of having adopted it. A woman, in whom he had tied five hemorrhoids with narrow pedicles, which were tolerably strained for this operation, did not at first experience a great deal of pain. However, five hours afterwards, he was informed that she suffered violent rectal pains, which extended along the canal. She was tied four times without material relief. At last Petit tied the ligatures, which could not be loosened, in consequence of their being encased so deeply in the substance of the swollen parts. The pain very soon subsided. The ligatures had only been applied four or twenty hours, but the piles had become black, and the skin covering their bases was cut through. Petit did not remove them without the least effusion of blood.

Petit also relates a case in which a patient, after tying had some piles tied, and of symptoms resembling those which take place in cases of strangulated bowel, notwithstanding the ligatures had been cut, as in the foregoing instance. After these two cases, Petit abandoned the practice of tying hemorrhoids. Mr. Kirby has mentioned two cases proving the effects sometimes arising from the ligature of piles: in one of these examples, the patient's life was saved with great difficulty; and in the other the operation was followed by

between and don't.—(On the Treatment of certain acute Forms of Hemorrhoidal Enlargement, p. 1—3, Nov. Lond. 1857.)

Mr. Henshaw, who prefers the use of the ligature, observes, that in performing the operation, it is not necessary to take up all the tumour; but that, if there are five or six, the tying of two or three of the largest will generally produce such a change in the texture of the rest, as will secure the patient from any return of the disease. After the ligatures are detached, he discharges the Secretions and applies cool lotions.—17th *Journal of the Lower Intestines*, &c. p. 215, vol. 2.

I believe, on the whole, that it is best to remove hemorrhoids with a knife, except when they are situated high up the rectum, where the piles are of large size and likely to bleed profusely. If a tumour be situated almost entirely beyond removal, which can rarely happen, a ligature might be put round it close with the aid of a double ligature. When the base of the tumour, however, is large, doubts of being brought up easily, and the surgeon prefers tying it, he should pass a needle armed with a strong double ligature, through the root of the hemorrhoid, and to one part of the ligature firmly over one side of the swelling and the other over the opposite side. When the base of the tumour is narrow, and the ligature is preferred, the part only to tie at first, without passing a double ligature through its middle.

Old hemorrhoids, which have been repeatedly in a state of inflammation, at length acquire a considerable degree of hardness. The internal extremity of the tumour becomes thickened, loses its natural softness, and forms a kind of cyst which prevents the tumour from bursting and bleeding.—(See *Traité de la Clinique*, vol. 4, p. 72.) In the end, it becomes encased by a kind of fibrous discharge. Its secretion now becomes by the use of emollient applications; and its extension is independently necessary.—(See *Lectures on Pathology*, vol. 2, p. 236.)

Amputation has occasionally prevailed, that the bleeding from piles is of a sanguine or critical nature, an evacuation, by which some poison is excited, which

is thrown off from the body. Hence, many patients have been advised to submit to the pain and annoyance which this disease occasions, rather than seek a cure. If the fact, that some patients have lost health after their piles have been cured, be received as sufficient proof of the disease having had a salutary effect, the doctrine must remain fully established. But before this inference should be drawn, it ought to be known whether the frequency of the fact is such as to warrant the conclusion; for it is not so obvious that the removal of piles places the patient altogether beyond the reach of danger and alarm, and no one will deny, that such operation frequently leads to improvement of the health. Were a patient to appear to suffer from the sensation of an internal bleeding from piles, leeches and even cupping-glasses might be applied.

A
DICTIONARY
OF
PRACTICAL SURGERY.

SURGICAL DICTIONARY.

H

HÆMIA. (From *haima*, blood, from its protruding form.) Singularly denominated, by the term *hemia*, a tumour, formed by the protrusion of some of the vessels of the abdomen, out of the cavity, into a kind of sac, composed of the peritoneum, which is pushed before them. However, there are certainly cases which will not be comprehended in this definition: either because the parts are not protruded at all, or because several are. It is only in two cases, first, the sac is watery; as, for example, when the hernia has been produced by the operation of great children or has been generated by a tumour of the abdominal parietes, or an abscess at a radical cure has been made with callosity. The sac is also sometimes rendered suppurative by laceration or ulceration. Sometimes, when occasionally protruded, are not included in the peritoneum, as the bladder and ovary: and when they are considerably distended, they draw after them the portion of peritoneum connected with them, which forms a sac into which other vessels may fall.

The hernia, however, which surgery has a duty to remove, is that which is properly speaking, only the result of pathological anatomy: that is to say, of actual corruption of the natural state of our organs, with such different diseases, which may depend upon a relaxation of texture, a displacement of functions, a relaxation of continuity, or a change of situation. It is from surgical pathology, that the most radical methods proceed, both, which making surgery is restricted, as defined, to so many varieties, each one, to which the art is indebted for the perfection of its operations.

There are indeed a certain number of surgical operations, for the purpose and safe execution of which more anatomical knowledge will suffice: but, in many others, the surgeon cannot proceed, himself assured, even though he be well acquainted with anatomy, unless he has previously studied the anatomical changes of position, and advantages of position, of which the parts are, which he is about to operate, are composed. If he has not this assistance is destructive upon all his plans, and consequently may destroy his patient, and thus his career, by a mistake, sometimes of a very serious and irreparable kind.

It is to be borne in mind, as a result of this study, it will be sufficient to take a view of the different species of hernia, and their various complications. As surgery, of course, would believe, that the intestine, singularly fixed in the right iliac, and the ovary bladder, situated at the bottom of the pelvis, could descend without being first, or considered as a displacement, as to pass through the abdominal ring, and descend even into the scrotum; that the same intestine, the ovary, could pass from the right iliac region to the scrotum, provided the right iliac artery was not fixed, and the right ovary could have been fixed protruded from the abdomen at the left abdominal ring, while the left ovary through the right one; that the liver, spleen, and lung could sometimes form the contents of a unilateral inguinal and femoral hernia; that the contents could escape half within the colon, and every at stake at the anus; that the contents could be forced through the diaphragm, and form a hernia within the chest; that the contents, or intestine, or both these parts together, could sometimes escape from the belly through the foramen ovale, or an anastomosis, even being caught in the diaphragm, such is under the human body, could suffer the same degree of strangulation, without the consent of the intestines being interrupted; lastly, that in certain circumstances, the intestine and contents could be in immediate contact with the testicle, within the tunica vaginalis, without the least laceration of the latter membrane. These and several other analogous facts (says Scarpa) are so numerous, that they would not be regarded as incredible, had they not been proved by anatomical observations on individuals affected with hernia: their possibility (repeats the experienced physician) would not even have been suspected, either by the anatomist or physiologist. (See Scarpa, *Traité des Hernies*, &c.)

The parts of the body, where hernia most frequently make their appearance, are the groin, the neck, the inguinal canal, and the upper and lower part of the thigh; they do also occur at every point of the anterior part of the abdomen, and there are several less common instances, in which hernia has even presented themselves at the foramen ovale, in the perineum, in the vagina; at the umbilical ring, &c.

The parts, which, by being drawn forth from the cavity in which they ought naturally to remain, mostly produce hernia, are either a portion of the intestine, or a part of the abdominal canal, or both together. But the stomach, the liver, spleen, uterus, ovary, bladder, &c. have been known to form the contents of some hernial masses. The small intestine is more frequently protruded than the large, and the liver more frequently than the spleen, in consequence of its greater proximity to the ring and crural arch. A part only of the contents of the tube is sometimes included in a hernia: the larger quantity may descend from a single fold in the whole movable portion of the coat. (See *Lamarcus on Ruptures*, p. 8, &c. 4.)

From these two circumstances of situation and contents, are derived all the different operations by which hernia may distinguished. If a portion of intestine alone forms the contents of the tumour, the case is called *enterocèle*; and if a piece of intestine only, externally; and if both intestine and contents contribute to the formation of the tumour, it is called an *exterior* hernia. When the contents of a hernia protrude at the abdominal ring, but only pass on here as the groin or femoral hernia, the case requires the name of *inguinal* hernia; but if the parts descend into the scrotum, it is called an *obscure* or *scrotal* hernia. The several or *femoral* hernia is the name given to that which takes place below Poupart's ligament. When the hernia protrudes at the navel, the case is termed by comparison of unobscured hernia; and external is the proper name to the scrotum, when it occurs at any other protuberance part of the front of the abdomen. The congenital hernia is a very particular case, in which the protruded vessels are not covered with a common hernial coat of peritoneum, but are lodged in the cavity of the tunica vaginalis, in contact with the testicle; and, as must be obvious, it is not raised, the hernia is generally, from its situation, or contents, but from the circumstance of its coming from the bow of birth.

When the protruded hernia is entirely in the sac, and subject of being readily put back into the abdomen, the case is termed a *reducible* hernia; and when they suffer no constriction, nor cannot be put back, owing to adhesion, or their large size in relation to the aperture through which they have to pass, the hernia is termed *irreducible*. An *intercostal* or *transversal* hernia, therefore, which we only cannot be reduced, but suffers constriction, so that, if a piece of

the pressure of the uterus and the pressure of one or several portions of the abdominal parietes. Indeed, hernias are seen occurring from the pressure caused by distension, in which one part of the abdominal parietes is more strongly contracted, and is made tauter while, from being cut, loose, or in a similar manner, becoming distended, causes an undue tension in one part, and so support to the distended part is lost. From a dist of both sides, with every considerable hernia, or even play upon both sides, as we have noticed a few instances, of the distension, and the tendency to support to the distended part, though there be not the best reason for supposing it to be a matter of the necessity. Various modes which offer different degrees, afford another proof of the same truth. Thus cancer is strong in a family and weak in others. One patient of our hospital, nearly cut, being capable of making any further reference to the pressure of the uterus, situated in the cavity of the pelvis, at length suffer those parts to give way.

With respect to the second proposition, that during the formation of a hernia, the increased force of all the abdominal parietes is, as it were, directed and concentrated against one particular point of the parietes, we see a proof of it in a fact that occurs in our observation every day. In order to observe ourselves of this, we need only notice what happens in individuals afflicted with hernia: if they cough, or sneeze, or make the slightest exertion, they instantly feel the strain at the swelling, increased, and labour to support the part with their hands. During the slightest efforts, which render the action larger, it is also indispensable, that the necessary is exhibited in the same proportion as the sensitive parietes. All the viscera have such a tendency to be displaced and carried towards the weakest part of the parietes of the abdomen, that even those which are naturally the most distensible, and are the most easily forced by the force of the pressure, are in fact here devoted into the hernia. Anatomical knowledge alone would never have led us to entertain a supposition of the possibility of these occurrences. Swifert and Palma have treated, in an excellent manner, the hernia, with a portion of the abdominal wall.—*Obs. Anat.* cap. 4; and *Nouv. Méthode de la Hernie* (Paris, 1780). Swifert, Cooper, and others have assigned the current in an internal hernia to the left side.—*De Hæm. Internis, in Hæm. Diap.* Chap. 10; *De Hæm. Internis, Anat. Pathol.* lib. 2, p. 28; *Observations de Hæm. Internis*, p. 5. Editors have seen the left side protrude at the right inguinal ring.—*Mémoire de Médecine*, t. 1, p. 173. It is proved by all these facts, that both systems are the most likely to be the most part of the parietes and neighbouring parts, are respectively liable to form hernia; and if even disfigurement reason happens without a considerable elongation of the parietes, large having their lower in their natural situation; how can we suppose that, that a more of intestine, pushed by down through the inguinal ring, does along with it the corresponding portion of the parietes? In order to explain this event, there is actually the supposition a partial relaxation of the hernia.—*From Practice of Medicine, par. 4, Scarpa, ed. in Thes.*, p. 37-41.

The same reason, which first produced the protrusion, is often of an ascending nature, as Mr. Lawrence has shown, are constantly tending to produce the hernia. The hernia becomes larger, in proportion as the pressure against the internal sac is increased, and more frequent. Hence, the great fact which it often creates in persons considerably pressing intestine outwards.—No instance of this is so proper as in the very remarkable instance of one patient in which it is noticed. Hence, the frequency of ventral hernia, and the possibility to cut one of a known hernia. The case of a hernia is likewise just dependent upon the frequency and situation of the opening through which the pressure appears. Hence, ventral hernia requires an actual protrusion, that some other hernia, or inguinal. The situation of the protrusion of the parietes is another cause of the distension of a hernia to a considerable size, while the situation and extension of the same having median hernia, in particular cases, as a check to the protrusion of the uterus, or in a distension of the abdomen, which are generally small. When the sac, after it has passed the parietes of the abdomen, is

situated among cellular, or adipose substance, it is pushed equally in all directions, and forms a nearly spherical tumour, being, however, generally rather flattened, and is inguinal and crural hernia. It protrudes through a canal, or is formed by distension, or is inguinal inguinal hernia, and even in those which have passed the ring, and are still confined by the strength of the parietes, cord. The freedom of the sac depends as it depends upon the situation, and then it is most of all, when the swelling becomes pyrexia. Large hernia of this kind often take place from the weakness of the parietes in directions preventing the hernia, and thus, at the last moment of the protrusion of a hernia of median location, the parietal parietes is displaced to the point where the hernia is free, but sometimes take place in quality, that the sac is forced upwards, and is confined by the contiguous parietes in a figure of more than three days standing. These abdominal hernia prevent the return of the sac into the abdomen, when the contents of the swelling are enlarged. The protrusion, which necessarily compounds the protruded system, generally retains the same size and delicate structure which characterizes that weakness in its natural situation. It is covered by other membranes, varying in thickness and structure, according to the part in which the swelling is formed, and depends the duration of the hernia, &c.—(See *Laws of the Hernia*, p. 28, Ac. ed. 4.)

Many interesting observations, in relation to hernia sacs, have been sufficiently explained by Cooper; and some of them are noticed in Mr. Lawrence's work. It is the cause which have produced the hernia, continues to operate, and further distends the parietes, as is proved by the strong adhesion to the transverse cord, the sac becomes thin by distension. It may give way partially by a kind of invagination, and thus become irregular in figure, presenting an appearance of small cysts, or secondary cavities. On the contrary, when the hernia does not adhere so strongly, and the mouth of the sac forms a thickened ring, the increased action of pressure may make the ring become, and a thick one will form at the new mouth of the sac. This process may be again repeated; and thus the sac presents one or more contractions, by which the protruded part may be compressed, and even invaginated. Inguinal and crural hernia are almost the only cases in which this occurrence can take place. When a hernia passes through a canal, a thickened ring may be formed at both orifices of the canal. If a hernia sac has been formed, and its mouth becomes thickened, a new protrusion may take place by the side of it: this may occur again. And thus we may have several contractions of two lateral cavities, or contractions of two or more secondary openings into one principal protrusion; or, the original opening cavity may be contracted, and form a small appendix to the subsequent protrusion.—(See *Laws of the Hernia*, p. 28; and *Cooper's Lectures on the Hernia*, &c. in *Series*.)

Hernia are more frequent on the right than on the left side of the body. This fact, as Mr. Lawrence has mentioned, does not depend on any disparity in size, between the apertures of the two sides, but must be referred to the varying form of the right side in those of the left which constitute the most powerful contour.—(See *Laws of the Hernia*, p. 28, ed. 4.) This subject has been particularly considered by Cooper.—(See *Anatomical and Surgical Treatise of the Hernia Abdominalis*, p. 20, Ac. 4th. Paris, 1813.)

The general situation of a hernia, which is noticed here, and the three strangulations, are as follows: In most of some part of the abdomen, most frequently descending out of the abdominal ring, or from just below Cooper's ligament, or else out of the external, and occasionally from various other situations, as will be presently explained. The swelling often inguinal suddenly, except in the circumstances above related, and if it is subject to a change of size, being smaller when the patient lies down on his back, and larger when he stands up, or holds his breath. It frequently disappears when pressed, and grows large again when the pressure is removed. Its size and position often is more after a meal, or when the patient is flaccid. In consequence of the unusual situation of the hernia, many patients with hernia are occasionally troubled with colic, constipation, and vomiting. Sometimes, however, the functions of the viscera seem to suffer little or no interruption.

Sometimes the contained part may be known by the symptoms. But, as Mr. Lawrence justly remarks, its discrimination is often difficult, and even impossible, when the hernia is not large and very tense. At, in cases of this description, the violent expressions and considerable changes in the figure and state of the thickened hernia are generally an affirmative standard for the hand.—(*Id.* *Lectures*, p. 92, et. 4.)

If the case be an aneurism, and the portion of intestine be small, the tumour is small, is compressible, but, though small, if the gut is distended with wind, inflated, or have any degree of tension made on it, it will be tense, resist the compression of the finger, and give pain upon being touched. On the contrary, if there is no intestine, and the tumour suffer no degree of inflammation, but the prolonged piece be of vital arterial supply, and the tissue of whatever size, the hernia will be soft, and so give no marked resistance to the touch; upon the patient's coughing, it will feel as if it were blown into, and, in general, it will be transitory only, and variable.—(*Id.*) A suppurative tumour it often makes with the word is ascending. An aneurism is also generally characterized by the universality of its surface and its elasticity.

If the hernia be an epiploic, or one of the omental kind, the tumour has a loose flabby, and a most unequal feel; it is in general perfectly indolent, is easily compressible, and (if in the stomach) it is compressible, and less round, than the swelling contained in the same situation by an intestinal tumour; and, if the quantity be large, and the patient asleep, it is, in some measure, distinguishable by its gentle weight. In very young subjects, the absence of a hernia is generally brooding; and that admits sometimes.—(*Id.* *Caput*, *Lectures*, vol. 2, p. 3.)

If the case be a retro-saphenous, flatly, and consisting of both intestine and omentum, the characteristic may be less clear than in either of the simple cases; but the disease may easily be distinguished from every other one, by the body in the habit of marking the circumference.—(*Id.* *Id.* p. 25.)

As the smooth slippery surface of the intestine generally makes it subject to slide out of the os cruris, we may infer, says Mr. Lawrence, "that if a portion of the contents slip quickly and with noise, leaving behind something which is less easily reduced, the case is probably an entero-epiploic."—(*Id.* *Id.* vol. 4, p. 47.)

On the subject of prognosis, Mr. Port remarks, that the age and constitution of the subject, the date of the disease, its being free or not free from inflammation, the symptoms which attend it, and the possibility or impossibility of its being reducible, necessarily produce much variety.

If the subject be an infant, the case is not often attended with much difficulty or hazard, the reduction being easy as well as the disease; and though often neglected, or trifled with, the lower way falls upon again, yet it is easily reduced, and attended without mischief. Mr. Port says seldom, because he has seen an infant, one year old, die of a strangulated hernia, which had not been down two days, with all the symptoms of mortified intestine. For other examples of mortal hernia in very young infants, refer to *Groch's Case*, *Hist.*, vol. 2, p. 21; *Laurance's Rupture*, p. 27, *Ann. 4*; *Edin. Med. and Surg. Journal*, vol. 3, p. 20, &c.

"If the patient be adult, and in the vigour of life, the consequences of neglect, or of bad treatment, are more to be feared than at any other time; the symptoms are obscure, and more trifling. The great and principal mischief to be apprehended, in an intestinal hernia, is an inflammation of the gut, and the obstruction to the passage of the aliment and feces through it, which inflammation and obstruction are generally produced by a stricture within the intestine. In very old people, the symptoms do not usually make such rapid progress, both on account of the laxity of their fibres, and their more frequent circulations; and also because their organs are most frequently of smaller size, and the passage is more easily dilated; but then, on the other hand, it should also be remembered, that they are by no means exempt from inflammatory symptoms; and that if such should render the activity of old organs so favourable circumstances in the treatment, which may become necessary."—(*Id.*)

If the disease be recent, and the patient young, im-

mediate reduction, and constant care to prevent its protrusion, are the only means which it is possible to obtain a perfect cure.

"If the disease be long-standing, has been neglected, or reduced to be frequently done, and has got so far as to make the aperture in the abdominal membrane the neck of the hernial sac, that neck is permanent, is large, which circumstances in general render the reduction less necessary and less likely to succeed; and also indicate all measures calculated to prevent it for the contrary, if the patient be young, or, though old, but generally less kept up, no immediate reduction is made absolutely necessary, as the risk of returning is greater from the supposed weakness of the aperture, and the progress of the age. If the tumour be very large and ancient, distinguished by induration, and also the effect in the system generally, and if other inconveniences be added to several, it may be necessary to attempt reduction, as it will be almost impossible to make judiciously proper medicine, and the bearing of the patient, in the attempt, may so irritate and excite them as to be mischief."

With respect to the continuance of the disease, and delivered, some death may be expected, though it would certainly not be right to prevent all attempts at reduction, so as to do nothing; it must be equally wrong to make no trial, without the hernia reducible or not; and if reducible, I should not, as it tends to be reduced without delay, and when applied. This opinion, however, seems to agree with the judgment delivered by Port in another place, it can be seen in the next section of this article.

With regard to the contents of a hernia, Mr. Port observes, that "if it be a portion of intestine only, and has been gradually formed, it seldom occasions much distress, though its weight will sometimes render it very troublesome. But if it be pushed suddenly, by effort or violence, that it is a considerable piece of the coil by accident displaced at once, it will sometimes prove painful, and cause very disagreeable constriction; the constriction between the intestine and the neck, stands out, and being such as to produce the sudden descent of a large piece of the first coiled part of the intestine, emitting, cold, and as the disagreeable symptoms arising from the distention of these vessels. When the piece of mass stopped is such a degree of intestine as to prevent the passage of blood through it, it will sometimes, by becoming gangrenous, be the occasion of very bad symptoms, and even to death; as I have seen this case occur, and thus, in a more ancient hernia, it may sometimes be subject to great hazard. But even though it should never be liable to the aforementioned evil, still, as it, though the portion of the coil should remain unimpeded in the scrotum, yet it renders the patient constantly liable to hazard from active matter; it makes every moment possible for a piece of intestine to slip into the same sac, and thereby add to the case of the trouble, and all the finger-making stress an intestinal rupture. It is by no means an uncommon thing that a piece of gut be added as a rupture, which had in many years been gently curbed, and for that point be strangulated, and require immediate cure."

"An old intestinal hernia is often removed, and reduced, more by gradualness than to the view of the prolonged piece of cord, then by its weight. It is very common for this part of the intestine, which passes through the neck of the coil to be compressed into a hard, smooth body, and of appearance of cord, while when it is loose in the intestine it has an irregular, and refers to natural shape; in this constriction is often produced, from the cord being in the part; and it is often seen sometimes that in old ruptures, the first, that I have witnessed, that for long months ruptured, rendered insensible by induration, being such because in this the circumference was small."

"In the case of old intestinal ruptures, which have long been down, and very frequently by a bag there is too very uncommon thing to have a pretty considerable quantity of fluid collected; this, as collected fluid and circumstances of the disease, is of different kinds and quantities, and seldom so much as appears in the section any particular attention to it; but, as Mr. Port says, it sometimes is so much as to occasion the

have been than could have been expected, but it was, in order to remove the inflammation arising from the weight and the distention of the viscera, which I have also seen become gangrenous by the violent inflammation.

"If the hernia is of the ventral kind, rarely, and the patient is not so much, we seek in general, stronger means to keep the bowels open in this case, and even production of vomiting when it has happened; for the cause of the pain is the gas which is expelled, the liquid the mucus, blood, and the more abundant in the vomitings. I have seen a fatal gangrene in a woman, which had not been noticed forty-eight hours, and it broke out just as expected, and this more than fifty years back."

Another observation made by Pott is, that "if the hernia is caused by a rupture in the intestines, then, it is in general more painful, than if a part of the viscera has descended without which will also require more address and more pain in the treatment. The reduction of a strangulated hernia by digital pressure will always prove more practicable than that of a more considerable, after it has assumed to a certain size and state, as the part contained within the former is liable to use almost at once also than within the latter, which duration has already been mentioned, or to undergo a kind of necrosis of the parts of the small and large intestines."

"Not that the parts within a more spiritual hernia are absolutely exempt from such an attack as may render their return into the belly impracticable, even when there is no stricture, for (says Pott) I have seen that part of the testis which has laid long to the neck of the sac of an old rupture, so considerably hardened and thickened, as to prove an insuperable obstacle to its reduction."

Upon the whole, we rather infer, that an intestinal rupture is subject to more symptoms, and a greater degree of danger, than an external one, though the latter is, by no means, exempt of either as it is a common mistake to say that had symptoms are more likely to attend a rupture internal, than one of external date, than the descent of a very small piece of intestine is more dangerous than that of a larger; and that the hernia, which consists of gut only, is in general attended with more consequence, than that which is made up of both gut and coat.—(See also *Lectures on Surgery*, p. 76, 77, et c.)

So, they coincide with Pott, in thinking the pain to be more considerable when the content is small. "I think it is not a bad general rule, that the smaller the hernia, the less time there is of treating it by the taxis. Long continued efforts to reduce a prolapsed intestine, are most likely to succeed in old and large hernia, where an adhesion has taken place."—(Ibid. *Lectures on Surgery*, p. 20.)

It is correctly remarked by Mr. Lawrence, that "the danger is greatest, when a rupture is accompanied at the moment of its formation. Hernia, which arises spontaneously, and slowly from predisposing causes, seldom become complicated. The intestine, in such cases, is never clasp, nor are the symptoms violent, because the parts concerned are weak and relaxed."

"The opening through which the parts protrude in hernia is more difficult than in others; the pressure of the contents which they have to pass, and the danger of the patient more urgent. The aperture is generally very small in femoral hernia; the kind of rupture is less, and the consequences are more fatal, particularly in the elderly. On the other hand, general, inguinal, and ventral ruptures are more dangerous than the former, external, or vaginal kinds."—(Treatise on Hernia, p. 124.)

CRAMPTON ON A HERNIA CAUSED BY EASY AND IMMEDIATE REMISSION, AND NOT ATTENDED WITH ANY TENDENCY TO A NEW STRUCTURE.

"This case," says Pott, "is very frequently met with in infants, and sometimes in adults, and is the only exception to both. In this kind, the descent, getting dangerous, but after the usual efforts to cry, and the gut is either easily put off, or returns and again, as soon as the child becomes quiet, it then is either easily repositioned, or we are obliged to resort to surgery by a forcible push or pull in the sac, and which, being subjected to such pressure, lays the foundation for future trouble and mischief."

"This is in great conformity with a common

opinion, that a strangulated infant were a steel trap; a generally spreading view, and which ought to be corrected. The time is so long in which such cases may not be more, or might not be applied, it is, when well made and properly put on, not only perfectly safe and easy, but the only kind of bandage that can be depended upon; and as a critical case depends greatly on the thickness of the hernial sac, and on being capable of being so compressed as possibly to allow, and thereby entirely close the passage from the body, it must therefore, appear in every case to be well given, however the trouble of thinking on the subject, that the father have the parts been made a descent, and the mother and nurse the danger of the persistence in the pressure the probability of such case must be.

"The usual method of acting must, for the same reason, depend in every case, it is a radical cure may reasonably be expected; that is, the prolapsed parts cannot be so soon returned, nor so carefully prevented from falling down again; every new descent renders a cure both more distant and more uncertain."

"As soon as the patient is returned, the time should be immediately put on, and when without sensation, care being taken, especially if the patient be an infant, to keep the parts upon which a pressure constantly washed, to prevent rotting."

"It is certainly necessary to say, that the surgeon should be careful to see that the hernia, as his success and reputation depend on such care. A truss which does not press enough to ward off the return of all, as it occasions loss of time, and destroys the patient of the hernia; and one which presses too much, or as an unwholesome part, gives pain and trouble, by producing an inflammation and swelling of the spermatic cord, and inflammation of the testicle."

"In such, where ruptures are of long standing, and accompanied by frequent descent, the hernial sac is generally firm and thick, and the aperture in the junction of the diaphragm muscle, large; the fundus and neck with which the parts enter into the belly when the patient is in an erect posture, and the little pain which attends a rupture of this kind, often renders the patient very labour under it various; but all such should be informed, that they are in constant danger of such symptoms their complaint, as may put them into great hazard, and perhaps destroy them. The passage from the belly must open, the quantity of intestine in the hernial sac is always liable to be inflamed, and, when it is so, it is bound by a stricture. The inflammation of this portion of the gut which is down, or such obstruction in it as may direct and enlarge it, may at all times produce such complications as may put the life of the patient in the most danger; and therefore, notwithstanding this kind of hernia may have been known for a great length of time, without having passed under complications or hazards, yet as it is always possible to become so, and that very suddenly, it is never to be prudent or safe to neglect it."

"Even though the rupture should be of the ventral kind, which considered abstractedly is not subject to that danger or kind of danger in which the intestines are liable to be so much, or by accident, the cause of it may be the same mischief; but while it keeps the mouth of the hernial sac open, it renders the descent of a piece of intestine always possible, and consequently always likely to produce the mischief which may proceed from thence."

"They who labour under a hernia that diminishes, that is, where ruptures have been generally down while they have been in an erect posture, and which have either gone up of themselves, or have been easily put up in a placid case, should be particularly careful to keep them from cool winds, and properly fitted for the mouth of the gut, and the opening in the diaphragm being well kept up, and the parts having been sent to descend through it, if the pad of the truss be not pushed up, and there be no other degree of difficulty in the spine, a piece of intestine will, in some posture, slip down behind it, and under the same production of that very kind of mischief which is sought to prevent."—(Ibid. *Tracts*.)

"This accident, so justly deprecated by Mr. Pott, is not uncommon, but, reasonably so, if the rupture pad of the truss be not fitted for the mouth of the gut, as he directs in this pamphlet. For if the internal surface of the pad be convex, as was formerly universal, and thought judiciously, and as indeed Mr. Pott

plandy is certain. It is so stated that a "piece of intestine should slip down behind it," because the pad is "fixed by the action of the sun," and the "opening in the tendon" is thereby made larger and more lax by the instrument itself, and the facility increased to a recurrence of the accident.

If on the contrary the rupture pad be centred on its internal surface, and stay by its own elastic resistance, directed to close the mouth of the sac, instead of opening it as it does when centred, this accident, or recurrence, and so often fatal, could not happen. This is an obvious improvement; but this is not a sufficient reason for its being passed over in silence by Dr. Cooper. See now on the article *Truss*—*Roller*.

Mr. Pott then comments upon the importance of having the parts completely exposed before the truss is applied, and upon the danger that may be incurred by laying such knowledge aside after it has been won some time; "there the natural closure of the ring, whereby the descent of the gut is rendered less easy, will also make the reduction more difficult, if a piece should happen to slip down;" and hence he insists, that a truss "should be long and successfully worn by all those whose cure of the disease the expectations of a perfect cure necessitate, many of the registered (white) being obliged to the slightest manner in which children in school are suffered to wear their trusses."

Beware the danger of strangulation, and the loss of all chance of a radical cure; when a scissile hernia is neglected, and allowed to remain down, there are other motives for keeping up the truss with a view, and preventing its increase or cure. The chief vice to which neglected hernia sometimes becomes, not only prohibits all active exercise, but, by preventing, in the male, the integuments of the penis, transmits the infection from the act of cohabitation, and gives rise to mortification from the discharge of the urine over the swelling. Probably, too, the truss may be affected by the pressure of a very large scissile hernia.—*Albergozzi de Caus. et Sym. p. 33, art. 12. Schenckius, Fernelius, Cyr. Schlegel, &c. p. 185.* Disorders of the internal functions inevitably attend these large ruptures, and increase in frequency and violence in proportion to the size of the swelling, and age of the patient. All the movable viscera of the abdomen gradually find their way into the hernial sac, as a rupture is entirely neglected.—(*Lectures on Diseases, p. 85, p. 4.*)

TREATMENT OF SCISSILE HERNIA, FROM DEGENERATION, AND CHARGED WITH TROUBLESOME OR DANGEROUS SYMPTOMS.

Mr. Pott, and all the best writers on ruptures, assume the incapacity of reduction, in most cases, either to the largeness of the quantity of the contents, an attending pain in their size and nature, or to adhesions, which they have contracted with each other or their containing bag. The reduction is also sometimes prevented by transverse tendinous bands within the sac.

Mr. Pott was also aware that ruptures are sometimes rendered difficult to be reduced, by the organs being contained in the hernial sac. Of this fact he was as much convinced, as the nature of such kind of things would permit. This is, by observations made both on the living and the dead. This statement, made by Pott many years back, deserves particular notice, because in truth is confirmed by the modern observations of Scarpa, whose very important explanations of the causes and difficulty of reduction, may be seen in the last edition of the *First Lines of Surgery*.

Mr. Pott has admitted to the kind of impediment to reduction, produced by the tumescence of the neck of the sac, when the hernia is long neglected, and suffered to remain in the scissile without any bandage to support it.

The same surface becomes an absorption produced by time, and coated thick with gelatinous matter, in the form and consistency, or texture of the contents, as an infrequent cause why neglected scissile ruptures become irreducible.

When a portion of omentum "has been suffered to remain for a great length of time in the scissure, without having ever been returned into the belly, it often happens, that although that part of it which is in the lower part of the hernial sac preserves its natural soft, adipose, elastic state, yet all that part which passes through what is called the neck of the sac is by constant pressure, coated with hard, thin, lacrymiferous,

corneous kind of body, incapable of being expanded, and taking the form of the passage, at which it is retained, exactly filling that passage, and rendering it impossible to push up the lower part, and reduce the contents."

The same process for incapacity of reduction is also sometimes met with in ruptures of the testicular kind, from an adherent parietal and/or part of the tunica, which has been supposed to be open for a great length of time in the neck of an old hernial sac.

The other impediment, which I mentioned, took place of old ruptures, at the contraction and swelling of the parts, either with each other, or with the bag containing them. This is common to both the scissile and the scissile hernia, and is produced by tight adhesions of the parts, which have been permitted to remain in contact with each other, or perhaps in contact from the mere contact only. These adhesions are more or less firm in different cases, but in the slightest will almost always be found an insuperable barrier to the reduction of the internal part, or the total sac.

Many, or perhaps most, of these hernial ruptures, become so by some time and neglect, and which at first have been reduced. But when they are reduced to this state, they are capable of no more than temporary application of a temporary bag, to prevent, or delay the inconvenience arising from the weight of the contents.

People in this situation should be particularly careful and to make any attempts beyond what is enough to keep at state of agility; they should take care to avoid the loaded or strained state, and to keep it out of the way of all labour, dress, pressure, &c. What is done is very easy, a soft quilted truss should be put on the bottom of the ruptured part, to prevent extension, and the truss should be frequently washed by the same patient, a bag of this kind, and in such circumstances, being sometimes of the utmost importance. They ought also to be particularly careful of the office of the internal organ, when that they drive by any irregularity of diet disorder it, and give themselves from being costive." Mr. Pott states, however, that the quiet, indolent state of scissile hernia is by no means to be depended upon; that things may happen to it by which it may become, as to increase in size, and even form adhesions of that part of the gut which is contained in the neck of the passage of the stomach and through it, a stricture made by the abdominal bands, even so what has been long down, or so a new portion which may at any time be added to it, are almost equal to it in showing the state of the case, as if the gut itself is in a painful state.

Indeed, the hazard arising from a rupture made in a piece of intestine, contained in the neck of a scissile hernia, is in one respect greater, than the attending one, that has been forced at some distance from the nature of the case it will hardly admit of any attempt towards relief, but the operation, when in these circumstances, must necessarily be attended with additional difficulty.

Among the ruptures which have been thought to be reducible, and treated as such, there have been some which, upon severe judicious and even patient attempts, have been found capable of reduction.

When this is suspected to be the case, the most method is by steady rest, in a supine posture on a considerable length of time, by gentle distension and the use of cathartics, so as to loosen the contents of the hernial sac, and to reduce them to the point of pushing back up into the belly.—(*First Lines of Surgery*).

There is likewise given an account of a man, who was originally cured of a rupture of the neck of the sac by six months' confinement in bed.—(*Crab. &c. p. 41*).

Let Edward Atwood relate a mention of several instances, which distinguished either by what the ruptured hernia had been treated to bed, and in some cases examined by Scarpa himself. Some of the instances have induced this species of rupture, and by frequent distensions, and repeated pressure, have produced or increased the size of the hernia, and it was then returned into the abdomen. Mr. Hays would have succeeded in this way.—(*P. 214*). But, if the causes prove substantial, when the rupture is long and old, or in the peritoneum, just within the hernial sac, the greatest objection to this method of cure is the want of an absolute criterion for distinguishing

when the parts do or do not adhere in the hernial sac, and, in advanced years, though one were sure that the viscera were not from the sac, the possibility of having the body, by the necessary operations, is also another objection.—(May's Clinical Surgery, p. 15.)

When the parts are thought ready to slide, keeping up a constant pressure on the tumour, by means of a temporary bandage, until it has time to heal, would be proper for promoting the absorption of the thickened parts by the hernial sac. Dr. A. Cooper has induced such results, after applying air to them; the great object of which is to expulse its producing a contraction of the viscera, and thus a strong and permanent compression of the tumour. Mr. Earl has succeeded in the impossibility of keeping up a general pressure on the swelling, by means of a bladder containing quinine, the quantity of which can be regulated according to circumstances.

Whatever any attempts of this kind succeed, a truss should be immediately put on, and worn without relaxation.

However, there are instances on record where the capacity of the abdomen had begun to diminish in the diminished quantity of the viscera, and when the contents of the lungs were injured, without complete cure from their contraction into the belly. In such cases, met with several such cases, in which he was obliged to take off the truss again. That has shown the possibility of a hernia of this kind passing final, the parts not descending again when the truss was removed, the viscera and vessels contracting, and preventing their return.—(Chirurgische Wahrnehmungen, vol. 3, p. 312; Medico-Chir. 1.2, p. 313.)

Mr. West remarks, that "an essential rupture, which has been so long in the system as to have become irreparable, is very seldom attended with any suppuration, considered absolutely; but it is constantly capable of being an occasion of an essential inflammation, and all its consequences; neither is it at all for the most part, cured, neither as time and nature, as is considered as to be capable of resolution, may be resolved in time, and what become phlegmatic, or organic, and the removal of a great deal of trouble." In a few instances, suppuration produced very bad symptoms indeed, cases of which are to be found in Gumpert, Bismuth, &c.

Sometimes, in old cases of enteric epiphora, the intestine is perforated, but the contents do not. In which case sometimes air is blowing up the part of bowel with a truss, the part of which must be so constructed as not to press on the intestines. Mr. Pott however, considers this method not often practicable, and should such a truss be used, he recommends great caution in its construction and application, not a small piece of gut, or wax, but being joined on by the truss, produce little mischief.

Irreducible hernia near of course be exposed to all the consequences of external injury and violence; hence, various cases are recorded in which the bowels have been burst by blows, falls, &c.—(Lewence on Hernia, p. 126, note 4.)

For instances of such accidents, Mr. Lawrence refers to A. Cooper on Hernia, part 1, Prof. p. 2; and to Trauma's by one the Forces of Nature, &c. p. 20. A case is recorded in this Hospital, p. 318, where a violent swelling caused a sudden return of a hernia which had been long supposed to be cured. The violent inflammation, which was borne to the point of suppuration.

SYMPTOMS AND TREATMENT OF A STRANGULATED, OR AN INFLAMMATORY HERNIA.—SEEMS TO BE THE MOST DANGEROUS AFFECTION.

"Difficulty of reduction" says Ross, may be owing to several causes. The use of the power of suction, on the inflamed part of the intestine, is a violent and necessary; so inflammation of the gut, or its distention by feces or wind; or the swelling of the membrane of the intestine, through which the contents pass. But in whatever cause it is owing, if the protruded body cannot be immediately reduced, and the patient without pain, it is attended thickly homogenized matter, it is called an irreducible hernia, a strangulated hernia, or a hernia with stricture.

"The symptoms are a swelling in the groin or scrotum, pointing the impression of the finger; if the hernia be of the scrotal kind, it is generally painful

to the touch, and the pain is increased by coughing, sneezing, or making efforts. There are also very hot symptoms, and, if they are not relieved, are also followed by others, viz. a sickness at the stomach, a frequent vomiting is sometimes to vomit, a passage of all the feces per anum, attended with a frequent hard and painful state of the bowels.

A patient thus circumstanced is in great danger, and demands symptomatic assistance. A stricture exists in the protruded part of the gut by the aperture through which it passes, in the immediate cause of all the bad symptoms, and of course the removal of such stricture is the only thing which can bring relief. This object can only be accomplished by separating the bowel back into the abdomen, or by tying the parts which form the stricture. This former plan is always the most desirable, when practicable.

We may proceed to notice the various methods to be adopted for the relief of a strangulated hernia, so as to obtain the best chance of doing away the necessity of an operation. After treating of the various methods, a few remarks will be offered on the order in which the treatment should be put in practice.

First.—This is the first step to be taken in the treatment of a hernia with the hand. It is much promoted by the position of the body, which, whenever thought should be placed on an inclined plane and the thigh bent towards the trunk. Dr. A. Cooper advises the same practice, observing that this posture by relaxing the fibres of the thigh, relaxes also the aperture through which the hernia passes. Every degree of tension and relaxation of the femoral duct, must necessarily be attended with a corresponding change in the abdominal cavity. But degree of the thigh, besides relaxing this duct, also relaxes the abdominal internal liver, and pons muscles. In cases of inguinal hernia, the pressure made on the mass by the hands of the surgeon, should always be directed upwards and downwards, along the course of the spermatic cord; and Dr. A. Cooper advises it to be continued above a quarter of an hour.—(The Treatment and Operation of Hernia, &c.)

As the femoral hernia passes downwards and then forwards, the pressure must be directed first backwards and then upwards. In scrotal and ventral hernia it is to be made equally backwards. No clothes should ever be used, for, besides being irritating, it greatly aggravates the inflamed state of the contents of the hernial sac, and has been known even to burst the intestine.—(See Cooper on Inguinal Hernia, &c. p. 23.)

Besides bending the thigh, care should also be taken to make it steady, which will have great effect in relaxing the femoral duct, and tenders of the external oblique muscle. Suspension of the patient over the shoulder of an assistant has been thought to facilitate reduction; but have tried it often says Mr. Ross, but have not found it to be of much superior efficacy to some authors have represented.—(P. 144.)

The treatment of gently pulling the intestine downwards, or a little way further out of the ring, previously to the attempt to reduce the hernia, has been suggested.

—(See Ross's New Method of the Treatment of Hernia, &c. Part. Jones, Nov. 1824.) This plan, I believe, is not exactly new, and it is noticed by Mr. Lawrence; who says, that a half an hour's rest, when the difficulty of reduction is owing to an inflammation of local matter.

The removal of a piece of intestine is generally produced by a local cause, caused by the passage of air through the intestine. In scrotal and ventral hernia, and then in inguinal. The symptoms point up next to the very last position, which must be actually pushed through the aperture. If the hernia should not succeed at first, it will afterwards alter the worst, such, bleeding, or suppuration. Small hernia, being attended with the least tension, the most difficult to reduce, and, for the same reason, great attention to be often paid to the time, as inguinal hernia is the most subject. The time becomes less likely to succeed, the longer the intestine remains here been seen, because adhesion is liable to form. Mr. Lawrence observes in 1824: "When the rupture becomes painful, you are no longer justified in proceeding to attempt at reduction by the hand. A sufficient pressure cannot now be obtained, and the force which is required only tends to increase the inflammation, and to hasten the approach of gangrene. At this period, the operation is required, and should be performed without

frequently is obtained, by the good effects of bleeding, purgative medicines, and opiate, and foodies applied to the belly. Mr. Lawrence has justly observed, "One system, as it very frequently happens, the aid of the surgeon is not required, until the complaint has lasted for some time; and of the various remedies with the typical use of which should be immediately resorted to, in circumstances will not admit of delay in the performance of less powerful remedies."—(P. 146, vol. 2.)

Every man who has seen much of hernia, will immediately recognize the propriety of the following antithesis of the experienced Mr. Hay.

"I can scarcely give a negative form to the necessity of an early recourse to the operation, as the most effectual method of preserving life in this dangerous disease. If Mr. Hay's opinion be true, that the operation, when performed in a proper manner, and in due time, does not prove the cause of death above than perhaps once in fifty times; it would undoubtedly preserve the lives of many, by performing it almost as soon as the disease is recognized, without attempting the dangerous by spending much time in the use of means which cannot be depended upon for success.

"I have twice seen third-stage hernia fatal in about twenty-four hours. In such cases, it is evident there is little time for delay. A physician, who is competent to perform the operation, is not perhaps consisted of all the intestine is at the point of being asphyxiated, or actually in a state of gangrene. The disease is one which he is, therefore, in making himself. But when the patient is brought to a point of time of using the best mode of treatment, I am satisfied that his success will be the greatest when the operation is not delayed. This, at least, has been my own experience. When I first turned upon the profession of surgery in the year 1811, the operation for the strangulated hernia had not been performed by any of the surgeons in Leeds. My seniors in the profession were very kind in affording me their assistance, in calling on this complaint when such cases occurred, but we considered the operation as the last resource, and an improper still less dangerous measure. My own dictatorial mode of practice, I lost three patients in five, upon whom the operation was performed. Having more experience of the efficacy of the disease, I made it my custom, when called to a patient who had laboured two or three days under the disease, to wait only about six hours, then I might try the effect of bleeding if this evaluation was not forbidden by some pressing circumstances of the case; and the relaxation, in this mode of practice, I lost about two patients in three, upon whom I operated. This comparison is drawn from cases nearly similar, leaving out of the account those cases in which a progress of the disease had taken place.

"I have now, at the time of writing this, performed the operation thirty-five times, and have often had occasion to lament, that I had performed it less late, but never that I had performed it too soon. There are some cases in which, that it is not advisable to lose any time in the trial of means to produce a reduction. The delay of a few hours may cut off all hope of success, when a speedy operation might have saved the life of the patient."—(P. 141, &c.)

To determine the exact moment, when to give up the trial of the preceding measures, and to have recourse to the operation, is certainly difficult; but, as we can doubt that it is generally better to operate too early, than too late.

All hernia, even, in general cases, liable to many causes, in inflammation, little or none should be allowed to the trial of any plan, and the operation should be done without the least delay. In such a situation, we have full time to try the effects of every thing or all body is secured. The symptoms, which could be given up, in finding moment in the operation, arise from an attack of inflammation in that part of the intestine contained in the hernial sac, and from its spreading into the abdominal cavity. It is so proper to this situation, that we ought to hope the performance of the operation. Dr. A. Cooper considers pain as pressing the body, and therefore, as a sign of inflammation which points out its immediate removal. He adds, "Indeed, there is scarcely any period of the symptoms, which should demand the operation; for, even if inflammation has partially begun, the operation may be the means of saving life, by preventing the study

operation of progressive parts."—(On Surgical and Congenital Hernia, p. 27.)

Whenever the surgeon has entered in finding the parts, without having recourse to the knife, if the symptoms of pain, inflammation, &c., can be kept under control, they will not always prove immediately afterward. As they probably depend on the reduced blood having been inflamed by the pressure, the body should be kept open, and the diet and regimen should be free and sparing, while the best chance of cure can be taken. In such a case, if all complaint is slowly removed from the abdomen, and the pressure in the groin free, and without trouble.—(P. 141.)

THE FIRST SYMPTOM IS A STRANGULATED HERNIA.

The earliest symptoms have been already given, viz. "pressure in the groin or scrotum, attended with pain, not only in the part, but all over the body, and swelling a swelling and distention of the abdomen, with some degree of fever." These are the first symptoms, and if they are not opposed by the return of the intestine; that is, if the attempts made for this purpose are not successful; the symptoms become more troublesome, the swelling more frequent, the pain more intense, the tension of the belly grows more feverish, and a general inflammation arises in which is very terrible to look. When the inflammation of the point, no time is to be lost; a very little delay is now of the utmost consequence; and if the one single remedy which the disease is now, cannot be so soon administered immediately, it will prevent the every other attempt. This remedy is the operation, whereby the parts engaged in the situation may be set free. If this be not now performed, the swelling is soon increased for a considerable time, and a frequent pulsing up of bilious matter, the tension of the body, the swelling, and fever being now considerably increased for a few hours, the patient gradually becomes perfectly free, the belly subsides, the pain, from having been fixed, felt, and constant, becomes less, languid, and generally intermittent in the skin, especially that of the trunk, and last but not least, the eyes have now a large and a glowing, a light being ready to be described; the tension of the part disappears, and the skin covering it sometimes shows the natural colour for a brief hour; but whether it be or does in colour it has an appearance that is peculiar to the flesh, which will easily be perceived by all who have attended this, but is a sign that it is nearly as dead as by words. This condition is the one in which strangulation is most common. In this case, the gut either goes up spontaneously, or it is drawn with the greatest degree of pressure; a swelling is made by study, and the patient is generally recovered at the end of the day; but this phenomenon should be time, for the surgeon and the rest of the family, and increasing, with the addition of symptoms upon the abdominal tenderness, the tragedy soon follows."—(P. 141.)

According to Sir Astley Cooper, one of the most common symptoms of a strangulated hernia is pain above the diaphragm, followed by constant vomiting. The patient is soon troubled with swelling and tenderness. He feels a great inclination to lie down, but cannot succeed in his attempts to rest the feet. There is some pain in the scrotum; and a great deal of the gut where the stricture is situated. Although the disease becomes considerably distended with air, and distension not arising in the first instance, but from the pressure being increased, he is asked by the nurse to be allowed to give in for any pain. The vomiting becomes more frequent, and the patient is often forced from the stomach, and when he is brought by water to the water, the patient is in the first stage. A dyspepsia will sometimes arise from a partial freedom of the gut, but the operation will be necessary. When the abdomen is in this state, but accompanied with pain, and when there is frequent vomiting of the mucus, the patient is not in the second, and very different, but, in the next stage of the symptoms, when the abdomen is not only free, but painful on being touched, the patient is extremely weak and feeble. The vomiting and excessive tenderness, and the patient is pale, and covered with a cold perspiration. The patient becomes very weak, thin, and is greatly a little inflamed on the surface of the skin.

With regard to the laceration which takes place, and which has recently been considered as a sign of the presence of gangrene, Mr. John Cooper declares, that it is not known, and he knows patients having had it for many years, and yet recovered after the operation. Hirsch says sometimes gangrene occurs several days after the latter proceeding, and, at the time, healing does more good than any other remedy.—(*See LANCET*, vol. 2, p. 123.)

ANATOMY OF UMBILICAL HERNIA.

This subject must necessarily precede the account of the operation, which would otherwise be unintelligible. It is chiefly in the anatomical information relative to hernia, and in the mode of operating, that modern surgeons have achieved superiority over their predecessors, for, before Lisfranc, Cooper, Hey, Lawrence, Cooper, Sharpey, Hirschbach, Langenbuch, and Cooper published their several works on hernia, the anatomy of the disease was but imperfectly understood.

The tendinous fibres of the aponeurosis of the external oblique muscle, as they run downwards and downwards towards the pubes, separate from each other so as to leave a triangular opening, called the abdominal ring, which is certainly more extensive in the male than in the female subject. The upper and lower pillar (as it is termed) of this aperture is composed into the symphysis of the pubes, and is the outlet of the inguinal canal, and water and vessels in the sheath, is chiefly a continuation of Poupart's ligament. *Langenbuch*, *Sharpey*, *Hey*, *Cooper*, *Lisfranc*, and *Hirschbach*, p. 4, and as far as the angle and crisis of the same bone. Some maintain there exists the separated outer angle of the ring, others as distinct the triangular aperture of the whole aperture; these are said to be very varying in all persons. The anterior and oblique line of the aponeurosis of the internal oblique muscle joins the tendons of the external oblique; the posterior and inferior part runs from the transverse arch, but the lower portion of this tendon, together with the corresponding part of the transverse, goes behind in front of the transverse muscle. Thus the latter border of the oblique inguinal and transverse, which originates from the upper part of Poupart's ligament, lies behind the outer pillar of the abdominal ring. Mr. A. Cooper did not consider that a third fascia proceeds from the lower edge of Poupart's ligament, and spreads over the posterior surface of the transverse muscle. This fascia forms the only partition between the peritoneum and the outer opening of the abdominal ring, and would be useful in evidence, against those who would probably be such more ignorant. The partition, in operation, however, is used by *Sharpey* to be formed by the aponeurosis of the internal oblique and transverse muscles, while *Langenbuch*, who has named the small muscle point situated directly behind the outer opening of the abdominal ring, its crural surface, distally placed, that it is formed by delicate fibres and transverse line of the internal oblique muscle (*Ueber die Hernie*, p. 4, *de Litteris* and *Schreibweise*, p. 4) and that behind this is the weakest part of what he terms the internal inguinal ligament, in the tract of which is the peritoneum, with the intervention of a very loose stratum, because—(*Op.* vol. 1, p. 58). The external inguinal ligament of *Langenbuch* is described as being the same thing as the above fascia joined, and by Mr. A. Cooper. The point of the statement is that of the three weak places in the inside of the inguinal region, either hernia was liable to occur, yet, weak as it appears to be, it is the most common situation of such tumors. A communication has been made, not in a hundred cases of inguinal hernia, but in some at the point last specified.—(*Dr. J. Deschamps, Des hernies, des Brûlés, de M. de la Roche*, 1811). Mr. Lawrence observes, that if we take the three communications from the vessel with epineurium, we shall find a divided lamina, and the peritoneum, an internal and external which have between them a considerable interval just in the middle of the stratum. The fibres of these, which is the strongest, and most decidedly fibrous, is connected by the lower edge of the outer margin of the rectus, and in the inferior margin of the tendon of the oblique inferior and transverse, and both are gradually lost above, between the peritoneum and transverse.—(*On Ruptures*, vol. 4, p. 123.)

The spermatic vessels, joined by the vasa deferens,

run in front of the epigastric artery, very near the place of its origin. They then pass through the above fascia, go under the edge of the external oblique and transverse muscles, and last obliquely downwards and forwards, between the above fascia and aponeurosis of the external oblique muscle, to the opening of the ring. When arrived on the smooth surface, immediately behind the ring, they describe an oblique angle, and pass upwards and downwards into the scrotum.—(*Langenbuch*, *op. cit.* p. 5.)

There is one point that the spermatic cord, before it actually enters at what is named the abdominal ring, runs through a kind of canal, in which the spermatic inguinal is often applied. The shape of the canal of the ring, through the abdominal partition, was well known to, and elegantly described by, Albinus; Gombert makes distinct mention of it in his account of a *Nerv. Abdom.* of opening for *Fluvius Hernia*, p. 12, 22; but the A. Cooper has the merit of having given the earliest correct account of the inguinal canal, in reference to hernia; a subject rendered complete by the more recent elucidations of *Langenbuch*, *Sharpey*, and *Langenbuch*.

The abdominal ring is then only the outer opening of the canal or passage, through which the spermatic cord passes before it enters. The manner, in which the vessels first pass, in the most common cases of inguinal hernia, is situated about an inch and a half from the abdominal ring, in the direction towards the superior external inguinal process of the ilium; or, according to *Langenbuch*, the inguinal canal is situated an inch and a half as length, the average distance of the outer pillar of the abdominal ring, from the lower pillar of what he terms the posterior ring, being about sixteen lines—(*Op.* vol. 1, p. 115). This lower opening is often termed the posterior ring, and its upper border is fixed by the lower edge of the external oblique and transverse muscles, which can be easily felt with the finger, introduced upward and carried into the abdominal ring.

The precise point at which the hernia most commonly issues, is the pubic arch, and the inguinal ligament, in the form, in the communication of the vessels inguinal with the peritoneum, and, in the adult, is the junction of the spermatic cord under the transverse muscle. In the second state, the peritoneum protrudes at this point a small funnel-like depression, the depth of which increases in proportion to the spermatic cord is pulled forth above downwards. It is this small pouch, this sort of digital appendage, whose progressive augmentation constitutes the hernial sac. Resting upon the anterior surface of the spermatic cord, it first makes its appearance under the inferior edge of the transverse muscle; thence it extends itself in the separation of the inferior fleshy fibres of the internal oblique muscle, always following the spermatic cord, in front of which it is situated, and after having, in this manner passed through the whole of the canal, which extends from the first region to the pubes, it lastly protrudes at its external orifice, which is the inguinal (or abdominal) ring, properly so called. In all new tumors, the hernial sac, as well as the spermatic cord, is situated above the femoral arch, the direction of which it follows. The tumor which is a tumor is of a conical shape, the apex of which is towards the flank, and the base in the external orifice of the ring.—(*Sharpey*, *Treatise*, by *James*, p. 44, 45.)

The spermatic artery, runs behind the spermatic cord, along the lower margin of the internal opening of the above point, then upwards and forwards, so as to pass at the junction of half an inch, or an inch, from the upper extremity of the outer opening, or abdominal ring.

In human cases of inguinal hernia, the uterus, protruded under the opening of the inguinal canal, is over the spermatic cord, and forms a tumor on the outside of the abdominal ring.

When the clitoris is very extensive, the above described digital process of the peritoneum, but do not protrude through the abdominal ring, the case is nevertheless treated as if it were a regular inguinal hernia, and complete when they pass out of this opening. The vessels may continue for a long while again, within the inguinal canal, and even become strangulated there; sometimes, also, they are prevented from passing farther towards the ring by a too kind of impediment; and, in the circumstance, in the literature, have any addition made

to its contents, it may expand between the external and internal oblique muscles, as Henslow has an opportunity of seeing in the body of a snake.—(Edinburgh Dispensary, &c. *See Lecture and Demonstration*, p. 285.) The distention may take place either at the internal or external opening of the inguinal canal. In most and usual hernia, according to Sir A. Cooper, the inguinal ring is most frequently situated in the lower opening, in large old persons, at the abdominal ring. Here, when the parts completely protrude out of the lower opening, the distention may exist at the other end; but this may occasionally be vice versa, viz. the distention existing at the upper opening.—(See *Lectures on Ruptures*, p. 163, *art. 2*.)

The hernial sac descends through the abdominal ring, over the spermatic cord, and is covered by a tunica, cut off from the body of the external oblique muscle. Beyond this fascia, the transverse muscle is situated, over the sac, which, after it has descended a certain way, becomes the internal inguinal, as well as the spermatic cord.

As the spermatic artery naturally runs first behind the spermatic cord, and then along the inner margin of the apertural opening of the ring, and as the vessels are projected over the cord, they must be situated on the outer side of the artery, which runs first behind the neck of the sac, and then on its inner side. Hence, the inner margin of the sac, when situated on the side towards the abdomen, seems to be formed, as it were, by the neck of the vessel.—(See *Lectures*, p. 178.) Thus this is the ordinary situation of the spermatic artery, in relation to the inguinal hernia, as testified by the constant testimony of Cooper, Elliot, Desault, &c. &c. See A. Cooper, Henslow, Scarpa, &c. and by preparation to be seen in almost every museum.

In recent inguinal hernia, the internal and external openings of the ring are at equal distance from each other, the first being situated slightly upwards and outwards in relation to the other; but the pressure of the protruded vessel gradually forces the apertural opening more towards the pectus and venter in the abdominal ring, so as to render the posterior side of the neck of the hernial sac, and of the inguinal canal, very short.—(Henslow, p. 28.) Thus, in large hernia of long standing, the spermatic artery becomes situated nearer the pectus than in the natural state.

Though this is the ordinary direction in which a hernia protrudes, there are occasional variations. In some of these the vessels, instead of descending through the apertural ring, are at once forced through the abdominal ring itself, and the opening into the body as they direct; the hernial sac, instead of passing to the external side of the spermatic vessels, as is usual, now lies outside them in the pectus; and the spermatic artery, which is commonly situated behind, here passes its course, in front of the sac, as its usual course from the vessel and outer margin of the abdominal ring.

The following is Scarpa's description of the displacement of the spermatic artery in the greater number of cases of inguinal hernia:—"This artery, which, in the natural state, runs about two lines from the abdominal ring, has no sheath and direction is changed, in subjects affected with hernia, thus it crosses the posterior part of the neck of the hernial sac, and is pushed from the outer to the inner side of the abdominal ring. In subjects who presented the recent or old displacement, it is necessary to consider what I have designated one of the inversions of inguinal hernia, and of the manner in which the spermatic cord crosses the spermatic artery. The hernia begins to form in the very place, where the spermatic cord passes under the inferior margin of the transverse muscle; and this place is rather near the flank, than that where the spermatic artery passes towards the rectus muscle." In its progressive extension, the hernial sac necessarily follows the same track as the spermatic cord, which is situated upon its anterior surface. As the sac already explained, this cord crosses the spermatic artery; consequently, the hernial sac must necessarily pass with the cord above this artery, before protruding from the canal of the abdominal ring. At the same time, the internal bottom of the hernia lying high up, and the inguinal canal obstructed by the inguinal ligament of its own nature to each other, it follows that at the point when the

hernia begins to make its appearance in the groin, the spermatic artery is unavoidably situated behind the neck in the hernial sac, and is pushed from the outer to the inner side of the ring. Let us suppose a piece of string to be passed from the inside of the abdomen into the scrotum, all through the inguinal canal, and the middle of the hernia; and that this string is pulled on so as to bring out the internal orifice of the hernia, which is situated beyond the point where the spermatic cord crosses the spermatic artery; this artery will necessarily be forced to be carried from the outer to the inner side of the neck of the hernial sac. The same thing happens from the effect of the contraction of the hernia. The removal of the spermatic artery, from one side of the ring to the other, (says Scarpa) is a phenomenon which may be regarded as a demonstration in the inguinal hernia. I have examined the bodies of a great number of subjects affected with the hernia of hernia, and it has been only in a very few that I met with the spermatic artery remaining in its usual situation on the outer side of the abdominal ring. In investigating the manner of this exception, I have observed, in all the individuals who presented it, a very remarkable weakness and looseness of that part of the abdominal parietes which extends from the flank to the pectus. In all, the displaced artery had passed through the spermatic cord of the transverse and internal oblique muscles; not in the vicinity of the ring, as is commonly the case, but at a little distance from the pectus, along to the upper part of the rectus abdominis that is extraordinary, and disproportionate to the weakness of the hernia. I observed also, that the neck of the inguinal sac did not pass to an oblique direction, from the flank to the pectus, but that it protruded from the abdomen almost in a straight line, as behind forwards. In short, in these subjects, the usual cut-de-vent of the peritoneum, which contains the right of the hernial sac, had not begun to be formed under the edge of the transverse muscle, at the point where the spermatic cord runs outwards; but had passed through the spermatic cord of the internal oblique and transverse muscles, at a little distance from the pectus, and under the point at which the spermatic cord crosses the spermatic artery. The same hernial sac, having at this particular time ended into and united to the spermatic cord, protruded at the posterior border of the inguinal canal, without displacing the spermatic artery from its natural situation.

This species of hernia, properly speaking, is a variation of the ventral and inguinal. It resembles the former, inasmuch as the hernial sac passes in the situation of the transverse and internal oblique muscles; the latter, inasmuch as it passes out of the abdominal ring, conjointly with the spermatic cord.—(Scarpa, *Prove della Hernia*, p. 68, &c.)

Henslow particularly adverts to a singular species to be seen on the inside of the inguinal ring: "The upper boundary of it is as formed by the outer lips of the osseous arches; the lower by the tubercle beneath of the os pectus; and the internal margin contiguous by the crural vein and spermatic artery. Now, says he, when it is considered, that this artery necessarily obliquely upwards, because the lower margin of the ring, and the above transverse space, are placed too low to know on which side of the neck of the hernia the artery must be in the two species of inguinal, as well as the crural hernia; for, in these kinds, when contiguous to the above (inguinal) space, the artery lies at the outer side of the neck of the hernial sac; while, in every hernia, that takes place through the posterior opening of the inguinal canal, the same vessel is removed to the inner side of the neck of the sac. These species of hernia, Henslow applies the epithet lateral; and in the other, internal, according to the situation of the point at which they are protruded. By Sir A. Cooper, they are named oblique and oval, which are also very proper terms. The internal or lateral hernia is much more frequent than the oblique, and is said to occur chiefly on the right than the left side of the body; a circumstance coinciding with another observation, viz. that, in children, the neck of the osseous arch is longer upon the right than the left side.

The circumstance of there being two forms of inguinal hernia strongly confirmed one desirable hypothesis; surgeons have, that the spermatic artery lay somewhat at the lower extremity of the ring, side of the neck

operation is successful in preventing a radical cure, that he advised (p. 195) the employment of every operation for strangulated hernia.—(*See Lectures on Surgery*, p. 243, vol. 4.)

If the adhesion should be at the inner opening of the canal in the inguineal ring, Mr. A. Cooper advises the operator to introduce his finger into the sac as far as the stricture, and then to introduce a probe-pointed bistoury, with the flat part of its blade turned towards the finger, between the front of the sac, and the abdominal ring, till it arrives under the stricture caused by the lower edge of the transversalis and oblique internus. Then the edge of the instrument is to be turned forwards, and the stricture cut in the direction of the probe. This plan of not cutting the neck of the sac is liable to all the objections stated by Mr. Larrey, and is, indeed, the case, in which the stricture takes place at the abdominal ring. Mr. A. Cooper's history is a very proper one for showing the stricture, as it only has a small edge in a certain distance from the point. Perhaps on the whole, we may infer, that it is better to cut early and judiciously to divide the neck of the sac, instead of stricture straining it to this position at the ring as it may be. The method of cutting the stricture from within forwards is manifestly objectionable, as the ground of the risk of wounding the sac is in this mode being greater than that of wounding from surrounding the epigastric artery, when it occurs in an individual position, and derives from its regular course—a reflection which has made Dr. Hesselbach, (after an allusion to the practice—*Chirurgische Vorlesungen*, 4te Auflage, 1819.)

When the stricture is at the upper opening of the inguinal canal, the ring should not be cut, unless it prevents the descent from causing the sac simply united stricture, as happened in a case recorded by Mr. Larrey.—(*See Surgery*, p. 241, vol. 4.)

Being being made by the protrusion of the protruded part from the abdomen by the division of the stricture, we are to be immediately raised, if we find ourselves in this position. This does not necessarily follow by holding the finger. The intention is to be raised before the operation, but when a person of consequence is protruded, it is to be returned before either of the preceding steps. The hernia should always be reduced, unless it is found in a state of actual strangulation. It often appears as if there is no strangulation, but an individual person would deem it improper to return it into the abdomen. However, if such a situation should be reduced to a real strangulation, extensive parties are involved of the part. Mr. A. Cooper has judiciously cautioned the operator not to divide the sac, but to divide the stricture from the sac of the stricture. With these the protruded part is frequently found affected, and as they generally produce no permanent mischief, they ought to be merely dissected from the sac, purple, or not colored with which usually people, strangulation. To determine whether a discolored portion of intestine be positively manifested more pronounced pressing forwards the blood contained in the veins; and if they do again, it is looked upon as a proof that the bowel is still possessed of life.

In making a point of inflection from the abdomen, the surgeon should not introduce the plan without the ring into the stricture, and hold it there till another point has been reached. While motion is to be continued till the whole of the protruded bowel is reduced.

The employment of force is violence in the middle, which is more the violence of a hernia in the operation, than in the operation itself; a method the more permanent because with parts are seen as well as a state of inflammation. It is always better to divide the stricture than to divide the sac, as the latter is liable to get into a state of inflammation which is not good. Dissection of the hernia sometimes prevents the reduction, and when this is the only method, the part may generally be returned as well as its contents have been compressed into the reduced ring within the stricture. It is better, however, to divide the stricture from the sac, than to divide the sac, as the latter is not the same both for the abdomen in the manner just suggested.

Reduction is sometimes beyond the protruded part following in with other or to be reduced. The stricture is not only divided very freely adherent to the sac. The contents and inside of the sac are the parts which are most subject to become inflamed.

connected by adhesions. The finger will commonly turn for looking any more after adhesion which may sometimes place between the intestine and the side of the bowel sac. When these adhesions are firm, and of long standing, they must be carefully divided with the knife; an object which can be most easily and safely accomplished, in case they are strong enough to prevent the intestine to be divided a little way from the surface of the sac. But protruding the finger and stricture keep the external end of the lower and front surface of the intestine in contact, the protruded case is capable of separating the parts with a knife, as in the case of separating the intestine. In doing this, the finger should not be withdrawn so far as to cut near the bowel, but rather to leave the posterior parts of the sac, and return them with the intestine into the abdomen. Every post-operative treatment should always be repeated before the stricture is reduced. Mr. A. Cooper mentions that a total obstruction in the presence of the intestine in the sac has arisen from the adhesion of the two sides of a small intestine together.—(p. 31.) When the adhesions which prevent reduction are situated about the neck of the sac, and not of the epigastric view, it is best to make the wound through the skin and abdominal ring somewhat larger, so as to be able to separate the adhesions with more safety.

Having reduced the parts, the operator should introduce his finger, the purpose of being sure that they are fairly and freely returned into the abdomen, and no longer suffer constriction, either from the inner opening, from the ring, or the point just within the cavity of the peritoneum.

Sometimes a strangulated hernia is complicated with a hydrocele, a circumstance which may render it necessary either to cut through the inner swelling, or to limit the incision into the hernia sac, according to the following happens to reduce the whole of the front of the sac, as seen by Mr. Cooper and Mr. Stanley, or merely to stricture in front of the lower part of the rupture.—(*See Lectures on Surgery*, p. 243, vol. 4.)

TREATMENT OF THE HERNIA.

In an extensive hernia, this part of the body and the sac, however, it is to be reduced after the intestine. When, however, it is much distended, thickened and indurated, and frequently is found to be after reducing the contents of the sac in a hernia, the protruded part should be cut off. Its reduction in the stricture should be highly improper, both because an immediate strangulation of the protruded portion is necessary, in order to be able to cut the discolored, worn back into the abdomen, and because, when reduced, it would, in all probability, cause inflammation of the internal parts, and bring on dangerous symptoms.—(*See Surgery*, p. 422.)

The divided circumference should always be cut off with a knife; and if any of the intestine should bleed, they ought to be taken up with a tenaculum, and tied separately with a weak ligature. An extraordinary impression of hemorrhage from the cut end of the intestine has led many operators to put a ligature above this part, just above the divided portion, which they were about to remove. This practice cannot be recommended in any case. As a frequent effect of it is to induce a fatal inflammation, and even strangulation of the intestine, extending within the abdomen, as high as the stomach and mammae, such as we collect. Mr. J. Cooper has remarked, with great truth, that in the stricture the system should ever be preserved. The very object of the operation is to remove the contents from the protruded part, leaving free the presence of the surrounding tissues, and no more has this been done, than the surgeon includes it in a ligature, which produces a more perfect constitution than that which existed before the operation was performed.

When the operation has suffered strangulation for a few days (says the Larrey), it often becomes of a dark red or black color, and there is an appearance, on cutting it, as if some blood were contained in its substance. This, I believe, is the state which surgeons have generally described under the term of gangrene.—(p. 322.)

When put in this state, it does not bleed. I need hardly observe, that the dead part must be removed, and never reduced. Some have advised leaving the

happened in a case related in the *Ann. de St. L.* (Ann. 1. 22. p. 262.—*Th. Lancet*, p. 264, col. 4.)

Instead of such results, Mr. Lawrence judiciously recommended dilating the gut, and leaving the abdominal progress of the cure entirely to nature. The strings will be cut off, and the ends of omentum removed by the adhesive process in a state of organization, each other, the most favorable for the operation. Thus, there is a chance of the continuity of the intestinal canal becoming established again.

Whatever experiments it may be advisable to make in wounds with gunshot and division of the large intestine, I think, it may more judiciously establish, than the difficulty and danger of attempting to suture the bowels in cases of hernia.

OPERATION FOR VERY LARGE INGUINAL HERNIA.

When the tumor is of long standing, exceedingly large, perhaps extending half way down to the knee, and its contents have been mistaken of being completely reduced, the laborious and delicate procedure, provided a strangulation takes place, but not thinking long upon the internal sac, or attempting to reduce the parts.

The reason against the common plan of operating with cold circumscissors, are, the difficulty of separating all the old adhesions; the laborious dissection which would be entailed by laying open, as was a lance, and the probability that pain, as long protracted, might even bring on various complications, as related. J. L. Petit, and afterwards Dr. Monro, observed that it was not to be performed.—(*Chir. 4. 2. p. 212. Description of some Cases*, 1788.) Mr. Lawrence recommends an incision, at two or three inches in length, to be made through the instruments over the abdominal ring. The fascia, covering the hernial sac, is first to be exposed by dissection, and an opening made in it. This will permit a proper direction to be put under the hernia, and the peritoneal cavity may be conducted, by means of the probe, to the part that requires division. If great difficulty should be experienced in accomplishing our object in this manner, a small aperture may be made in the sac near the ring, where the hernia may be drawn with ease. The parts, after being thus divided, should be returned into the belly, by means of the syringe, if adhesions be not present: it, at all events, they present, should of being repaired in part.—(*Lancet*, as *Appendix*, p. 269, col. 4.) A very interesting case has been recorded, in which the foregoing advice was deviated from, and a large incision being made; when it was found that nearly a foot of the colon was contained in the swelling, and could not be reduced. The incisions could not be made: yet, as further treatment, the skin cut round itself in the direction of the swelling, which was diminished, and, in about six weeks the cure was completed.—(*See Journ. of Foreign Med. No. 11, p. 400.*)

OPERATION WHEN THE HERNIA IS SO SMALL THAT IT CAN BE MORE EASILY EXTERNALLY REDUCED THAN THE OTHER.

In this kind of case, there is little appearance of external tumor; consequently, the disease is very apt to be overlooked by the patient and surgeon, and some other cause assigned for the various symptoms. The nature of operating, in this form of the disease, differs from that in the common scrotal hernia. The incision will be made in the direction of the spermatic cord, and the stricture will be found at the internal ring.—(*See Cases in Legation Hernia.*)

TREATMENT AFTER THE OPERATION.

Emollients (over the bowels) should be immediately prescribed by means of cythere, oleum ricini, or small doses of emulsion of diagenia, dissolved in poppyseed oil; but the patient should not be allowed to quit the recumbent position, or get on his legs, until, as long as it is apt to bring on a protrusion of the bowels again.—(*Chir. 4. 2. p. 262, col. 2, p. 263.*) The best plan is to let the patient lie on his back for the first seven days of the cure. In the course of another day, if necessary, follow the effects of the first purgation, and moderate doses of the belly zone, as, heat and general fomenting, with the exhibition of liberal doses of sweetened oil with opium are strongly indicated. For some time the cure is to be kept. When symptoms

of inflammation of the bowels and peritonitis threaten the patient, general bleeding, leeches on the abdomen, emollients, blisters, doses of the oleum ricini, and cythere, are the means deserving of most dependence, and should be resorted to without the least delay. In these circumstances, the warm bath, sometimes recommended, I think is more likely to do harm than good, by the disturbance in which it subjects the patient. When all danger of permanent inflammation is past, and the patient recovers for food and drink, heat, warm, and a generous diet must be indulged. The effluvia from the throat, with opium, is the best medicine for quieting the disturbance of the stomach after the operation. Opium and cordials are the most eligible for checking diarrhoea. As the operation does not usually prevent the parts from becoming separated again, a truss must be applied before the patient leaves his bed, and afterward necessary more.

PROPOSALS FOR THE RADICAL CURE OF THE HERNIA.

Of restoring the patient, applying cordials, or of the operation of the peritoneal cavity, with this view, I have only to say that they are hazardous, and not at all calculated for the attainment of the desired end. A description of these methods may be found in *Prod. Wiggins*, &c.

The old operation termed the vaginal stitch was one of the most pressing plans. It consisted in passing a ligature under the neck of the hernial sac, close to the abdominal ring, and then tying that part of the sac so as to render it impervious to the adhesive inflammation that ensued.

The vaginal stitch performed in this manner, has been actually attended with success.—(*Revue*, vol. 2.) The scrotal cysts were cured by Bernard, on similar principles; and Denard actually cured nine cases of the spermatic by tying the hernial sac.

Scroeder cured two intractable inguinal hernia, in one instance, by cutting away the body of the sac after tying the neck.—(*Chir. Pathol.*, vol. 2.) In some cases, Sir A. Cooper forced matter away the sac alone.

Dissecting away the whole hernial sac, or even leaving it open, was by a formidable operation, compared with merely making a small incision down to the neck of the sac and applying the ligature. If the hernia were reducible, and the upper part of the sac could be reduced, it was by the ligature, all other more severe plans would be superfluous. However, Petit, Sharp, Acut, &c. would have been led to prove the danger and inefficiency of the vaginal stitch; though it is true that some of these surgeons operated rarely in the simple manner above mentioned.

Butler recommended tying the neck of the sac, with the view of producing an adhesion at its sides to each other; a plan which he says he found very successful.

From the account, however, which has been given of the anatomy of the inguinal canal, it is obvious that none of these methods could do more than diminish the size as high as the ring, and leave that portion of it which is within the inguinal canal. Hence, the neck of the tumor will remain open for the descent of the viscera. The consequences, and that of the character of bad and fatal symptoms from any operation undertaken solely for this purpose, and necessarily required for the relief of strangulation, are the grounds on which these experiments are now disapproved.

CHIRAL OR FEMORAL HERNIA.

Vesalio, who wrote, in 1538, has distinctly pointed out the nature of femoral hernia, which, with this, has been generally confounded with inguinal hernia.

The parts composing this kind of hernia always protrude under Poupart's ligament, and the swelling is directed towards the inner part of the bend of the thigh. The rupture descends on the inside of the femoral artery and vein, between these vessels and the pectineus, through the *crural ring*, or canal for the transmission of the crural vessels. And, as Hesselbach has remarked, the lower opening of this ring is covered by the pectineus, the cause of the disease, the peritoneum spread over it being gradually pushed into it by various occasional causes, so as to complete the tendency to hernia. The natural position of the bowels may be changed either suddenly or by degrees. As soon as the bowels have

once passed the water aperture, or what Clapier terms more properly the lower opening of the crural canal, the hernia has more room for extending itself forward, and to work side, and the integuments now become elevated into an oval swelling, the long diameter of which is nearly transverse.—(*Dissection*, p. 47.) Gibbier names the passage through which the crural hernia protrudes from the abdomen, the crural ring; the femoral ring; and Clapier, the crural canal.

Persons are particularly subject to this kind of rupture. It has been supposed, that women and of thirty married women affected with hernia have this kind; but, that not one of a hundred, unassisted, female, or one of the same number of men have this form of the disease.—(*ibid.*)

"The crural hernia," says Scarpa, "is frequently observed in women who have had several children; a very sedentary life; and still more rarely men. In the latter, the vessels are more easily engaged through the inguinal ring by following the spermatic cord, than they can descend along the crural vessels, and raise the margin of the apertures of the crural muscle from beneath the inguinal arch. In women, an opposite disposition prevails, in consequence of the weakness of the inguinal arch, which is deep, and slender is situated lower down, and enters the pelvis. It is in men, while, on the contrary, the crural arch is more contracting by reason of the wider form of the pelvis. Reciprocal reciprocity may, but be never met with the crural hernia in the body of any female subject. And, at various fathers, and children is female subject of rare occurrence.—(*De Sed. et Caus. Morb.* epist. 34, 13.) Clapier gives us no exact description of the manner in which it is formed in women, as Prefat. He is often observed for this kind of hernia in females, not only once in the same subject.—(*Method. et Therap.* p. 406.) Marshall and Walker have both seen, but a singleness of it in the dead body of the male subject.—(*Obs. Anat. Pathol.* cap. 4, p. 72. *Anglæ Comment.* Anat. p. 24, vol. 23.) Arnaud himself, to whom modern surgery is highly indebted for many important concepts on the operation for the strangulated crural hernia in both sexes, candidly confesses that he had never had an opportunity of dissecting a female of this kind in the male subject.—(*Suppl. Traité des Hernies*, p. 201.)

Scarpa had, at the disposal of a male subject in which there was a crural hernia, and he avoided himself of the opportunity of examining the parts with the instrument. He first injected the blood vessels; he afterward dissected the parts contained in the disease; and he has published an exact description of the particulars, illustrated by an engraving.

According to Hirschbach, the femoral hernia, though not known in Italy, is more frequent than is generally supposed, and often overlooked on account of its being very small.—(*Chir. des Visc. Visc. et des Lignes* and *Schubert's*, p. 47.) Thus, in a manuscript published in a modern work, an individual and femoral hernia were met with together in a gentleman sixty-three years of age. On examination of the body after death, a small piece of intestine forming a crural hernia was found unperforated and contained under an inguinal rupture and a mass of fat.—(*C. Ruff's Surgical Obs.* vol. 3, p. 375.)

Mr. Lawrence states that the femoral rupture is not so uncommon as many authors would lead us to suppose. He has seen many instances of it.—(*On Ruptures*, p. 435, note, of 4.) Dr. Brinkley, it seems, has also seen it rarely in thirty instances of it in the position of Ruysscher.—(*Observ. et Obs. Anat.* de, cap. 16. *Mem. de la Soc. de Med.* p. 42.)

According to the observations of Scarpa, and all the best modern writers upon surgery, the crural hernia occurs both in the male and female subjects in the cellular substance, which encompasses the spermatic cord before Propagator's ligament. The swelling follows the internal side of these vessels and gradually detaches into the fold of the thigh, between the sartorius muscle, and peritoneal muscles. "Many surgeons believe (says Scarpa) that the femoral ring, and the substance which it contains, are indistinctly situated above the crural vessels and the neck of the spermatic cord, and consequently between these vessels and the anterior superior apophysis of the ilium. But as far as my knowledge extends, this assertion is not supported by a single au-

thor description of the crural hernia in the early stage it is seen, that when the viscous has not acquired a large size, and its fundus is confined to a point, confined to the fold of the thigh, it passes in a straight line the crural vessels, and even the spermatic cord, as Walker says it once observed.—(*Anglæ Comment.* Anat. p. 24.) But it is not thence to be concluded, that the fundus in the beginning followed directly the crural vessels, much less between them, and the spermatic cord, as a process of the sperm. Another error it is supposed from the fact of the hernia less becoming detached from the fundus to the outer side of these vessels. If these two cases ever happen, they must be very rare, and the best authors who have treated of crural hernia concur in stating that in performing the operation, they have constantly found the viscous attached to the fundus of the crural vessels, but never on their outside. Even when the viscous, after acquiring a considerable size, is removed transversely over the crural vessels, the fundus of the hernial sac, and always being found upon the inner side, that is to say, between them and the spermatic cord.—(*Chir.* de, cap. 2, p. 2, *La Fige* *Chir.* d'Opérations de L'Anatomie, p. 226. *Petit* *Opusculum* *Chir.* de, cap. 226. *Moreau* *De Sed. et Caus. Morb.* epist. 34, 15.) Arnaud (*Mem. de Chir.* tom. 2, p. 70. *Goss* *De Hernia* *Tabula*, p. 70.) Bistram (*Practical* *Chir. Operations*, 2, 1, *Chir.* p. 226.) Pot (*Chir.* *Opera*, *Chir.* vol. 2, p. 124.) Denon (*Précis de Med. Chir.* p. 115—116.) B. Hall (*Art System of Surgery*, vol. 3, p. 357.) Kellner (*Traité des Hernies*, cap. 36.) Nodding (*Chir.* de, cap. 2, p. 166.) Lemaire (*Ann. Med.* p. 1, p. 185), and many other writers all concur upon this point. "It is support of this opinion (says Scarpa) I could give a great number of cases in my own, which I have collected, either in operating on crural hernia, or in dissecting the same kind of hernia in the bodies of many female subjects, and in that of the male from whom I have taken the engraving, also having had an opportunity of dissecting a female in whom crural hernia, which becoming one third of the way down the thigh, I observed that the neck of the sac did not encroach at all upon the crural vessels, but lay entirely on their inner side."—(*Surgery*, *Traité des Hernies*, p. 202, 203.)

The hernia, on account of its situation, is liable to be mistaken for an enlarged inguinal gland, and many fatal events are recorded to have happened from the surgeon's ignorance of the situation of the viscous. Mr. Lawrence states, in a hospital surgeon mistake a crural hernia for a glandular tumour, and the patient died, without any attempt being made to afford relief by the operation.—(*C. 423*, of 4.) And also Petit (*Traité des Mal. Chir.* t. 2, p. 223, &c.) A gland (as very largely enlarged by the gradual effects of inflammation; the swelling of a crural cystis comes on in a moderate and sudden manner, and when strangled, excites the train of symptoms already described in the account of the inguinal hernia, which symptoms an enlarged gland could never occasion. Such confusions were to be sufficiently detected earlier, though the feel of the two kinds of swelling is often not of itself enough to make the surgeon decided in his opinion. It is particularly remarked by Hirschbach, that while a femoral hernia is discovered, that is to say, within the gutta opened at the pannus, through which the parts descend, the disease presents itself as a round, firm swelling, on the outer side of which the femoral artery can be felt pulsing; that such hernia may be mistaken for an enlarged gland, and the case may only be terminated by the history of its origin and symptoms.—(*Chir. des Visc. Visc. et des Lignes* and *Schubert's*, p. 22.) A femoral cystis may be mistaken for a tumour, which the experience part of the swelling lies over Propagator's ligament. As the same and operation for the case may be performed, directly from above for the latter, the error may lead to very bad consequences. The femoral hernia, however, may always be distinguished, by the risk of the latter being Propagator's ligament cystis.—(*Chir.* *Opera*, *Chir.* de, cap. 2, p. 2, *La Fige* *Chir.* d'Opérations de L'Anatomie, p. 226. *Petit* *Opusculum* *Chir.* de, cap. 226. *Moreau* *De Sed. et Caus. Morb.* epist. 34, 15.) Arnaud (*Mem. de Chir.* tom. 2, p. 70. *Goss* *De Hernia* *Tabula*, p. 70.) Bistram (*Practical* *Chir. Operations*, 2, 1, *Chir.* p. 226.) Pot (*Chir.* *Opera*, *Chir.* vol. 2, p. 124.) Denon (*Précis de Med. Chir.* p. 115—116.) B. Hall (*Art System of Surgery*, vol. 3, p. 357.) Kellner (*Traité des Hernies*, cap. 36.) Nodding (*Chir.* de, cap. 2, p. 166.) Lemaire (*Ann. Med.* p. 1, p. 185), and many other writers all concur upon this point. "It is support of this opinion (says Scarpa) I could give a great number of cases in my own, which I have collected, either in operating on crural hernia, or in dissecting the same kind of hernia in the bodies of many female subjects, and in that of the male from whom I have taken the engraving, also having had an opportunity of dissecting a female in whom crural hernia, which becoming one third of the way down the thigh, I observed that the neck of the sac did not encroach at all upon the crural vessels, but lay entirely on their inner side."—(*Surgery*, *Traité des Hernies*, p. 202, 203.)

In the male subject, the crural hernia, in the early stage (says Hirschbach), is situated so deeply in the fold of the thigh, that it is difficult, even to the most experienced eye, to find its neck; and in acquiring its circum-

ferres with the extremity of the finger, the tendinous margin of the opening, through which the parts are protruded, was only in pendence with considerable difficulty. On the contrary, the inguinal hernia, however small it may be, is always *very* distinct. It is about half an inch above the bend of the thigh. In carrying the finger upwards we seek the umbilicus, margin of the inguinal ring can be easily felt as its circular fissure; and at the posterior part of the small tubercle, the cord composed of the spermatic vessels is distinguishable. When the crural hernia has acquired considerable size, its neck is always deeply situated in the bend of the thigh; but its belly and fundus remains an oval form, and whose great diameter is situated transversely in the bend of the thigh. Whatever may be the size of the inguinal hernia, it always presents a lobes (as if a pyramidal form, the base or lobes of which, the first being directed towards the flange, follows exactly the direction of the spermatic cord, and descends directly into the scrotum. Besides the pyramidal form, which it has attained a firmness and presents some others, which are peculiar to it, such as a *cone of cancer* and *hemorrhoid* in the thigh, and *ulcers of the leg, and even of the foot, of the same side.* The reason why ulcers and abscesses of the leg are particularly prevalent in cases of femoral hernia, is partly referred by Broussais to the circumstance of the femoral vessels and nerves, with numerous lymphatics, taking their course through the crural ring; and, according to his observations, "the inflammation and ulcer are especially great when the protrusion, at certain, which makes stronger pressure on the vessels and nerves than excessively happens in cases of carcinoma."—(P. 33.)

"In women, however (as Broussais observes), it is less easy to distinguish the crural hernia from the inguinal. In fact, the absence of the spermatic cord, and the more situation of the ring to the external arch, very easily occasion a mistake. Nevertheless, a woman may seem to possess to have a double inguinal hernia of the same side. While, of these two distinct, though neighbouring hernia, one may be inguinal, and the other crural. Anand (Memo. Med. Chir. t. 2, p. 605) mentions instances of such a mistake.—(*Surgery, Traité des Hernies*, p. 27, 28.)

This interesting article takes occasion to observe further upon the neck of the subject, that the position of the inferior part of the abdominal ring, which separates this opening from the internal and inferior angle of the crural arch, is so slender in women, that it is sometimes hard to distinguish the crural from the inguinal hernia, which is not the case in male patients.

Until a few years ago, the stricture, in cases of femoral hernia, was always supposed to be produced by the lower border of the external oblique muscle, or, as it is termed, Poyzant's ligament. A total change of opinion on this subject, however, has lately taken place, in consequence of the observations first made by Lisfranc, in 1833. "In the crural hernia (says he), the aperture through which the parts issue is not formed by two bands (as in the inguinal hernia), but it is a foramen almost fixed, proceeding from the internal margin of the crural arch (Poyzant's ligament), and an insertion into the branch of the os pubis, between this bone and the iliac crest. So that, in this hernia, the branch of the os pubis is marked more internally than the arteries, and a little behind; the vein, externally, and behind; and the external border of the arch, before. Now, it is this border which always forms the constriction."—(*See A New Method of operating for the Femoral Hernia*.)

The utility of knowing that it is not Poyzant's ligament which produces the stricture in cases of femoral hernia, is important; for we then know, that cutting the lower and inner blade of the external oblique muscle is quite *irrelevant*. This proceeding is the more to be reprobated, because the lower pillar of the abdominal ring, in both sexes, will be divided by dividing the internal epigastric artery and vein; and that the abdominal and crural rings will be made too near together, so that, large enough to make the future occurrence of hernia very likely to happen. In this case there is also considerable danger of the spermatic cord being cut. Cutting Poyzant's ligament, on the other side is attended with still more danger,

for the spermatic artery will infallibly be divided in its origin, and with all these hazards, the incision must be quite useless, unless carried on to the internal edge of the crural arch.—(*Generalist*, p. 75.)

The Indians, however, of several modern writers to make the stricture in cases of femoral hernia, is not attributed by the most careful observers, the femoral and Ligament.—(*Ann. Chir.* t. 9, p. 32.) The former party remarks, that a complete femoral hernia may be strangulated in two places, either at the point of its issue, or at the point through which the protrusion happens. Nay, they say, that the strangulation is sometimes caused by the outer opening, which is termed *ligament*, and they are convinced that the constriction is produced by dividing the muscle.—(P. 33.) And, in addition to these two modes of strangulation, it is to be imagined a third, in which the viscera are constricted by passing through some weaker point, or accidental opening, in the anterior part of the crural arch.—(*Revue Méd.*, p. 41. *Chap. de la Hernie*, p. 50. *Ann. Chir.*, p. 32, p. 135, et even through a rupture in the outer side of this passage, as we find related in the 17th lithograph of Larrey's treatise, "De l'Anatomie Pathologique."

I know of no English writer who has given a better account of the anatomy of the femoral hernia than Larrey.—(*New Med.* t. 2, p. 115, &c.) He observes, that when the direction is begun at the inside of the inguinal region, the following circumstances are noticed: after the removal of the peritoneum from the abdominal muscles, and from the psoas, iliacus, and the great vessels, the inner surface of the diaphragm will be seen at incision, which Clogier terms the *fascia transversalis*, and which is always a white gleaming appearance. From the place where the femoral artery and under Poyzant's ligament, while the superior space of the iliac, the ascending fascia is inserted in a strong fibrous band behind the outer surface of Poyzant's ligament, and a thin continuation of it is attached over the iliacus internus and psoas muscles, which it is named by J. A. Cooper and Clogier the *fascia obliqua*. The fascia of the transverse muscle covers the belly behind Poyzant's ligament, as completely as the peritoneum does, so that between the femoral artery and the anterior superior spine of the iliac bone, the *fascia transversalis*, which occurrence, is still farther preserved by the *fascia lata*, which, below Poyzant's ligament, is closely attached to the muscles of the thigh. By the point being thus shut up, the weight of a crural hernia on the outside of the femoral vessels is rendered quite impossible.—(*Larrey*, p. 41.) This part of the explanation very amply resembles that delivered by J. A. Cooper, except that the latter describes the iliac fascia, and not what Clogier calls the transverse fascia, as closing the point from the spine of the ilium to the crural vessels. But this difference is easily reconciled by the circumstance of J. A. Cooper excluding the name *fascia obliqua* behind the iliac vessels given by Clogier and Larrey.

Now the anterior superior spine process of the iliac, Larrey remarks, that the fascia of the transverse muscle has some minor folds, which pass over the upper and internal opening of the inguinal canal, of which they form, with more, the *ligament*, and are named by Lisfranc the *external epigastric ligament*. They enclose the femoral artery and vein, are connected above with the fascia of the transverse muscle, and below are continued into the fascia of the psoas and iliac muscles. When these fibres pass over the femoral vessels, they expand into a firm expansion, which, passing downwards, is immediately attached at the inner side of the femoral vein to the internal branch of the os pubis, close to the symphysis, and then joins the aponeurosis of the recti inguinali. The expanded portion of the expanding tendons, then, that continues along the crura of the os pubis to the sheath of the rectus, forms the lower portion of *Gruber's*, or the *fibrous*, or *external ligament*. The inner edge of this ligament is filiform and caprine, the concavity being turned towards the femoral vein. Now, when the fascia of the transverse muscle extends downwards on the outer side of the crural artery, to the fascia of the os pubis and iliac muscle, joins to the fascia of the psoas, between that vessel and the anterior superior spine process of the iliac, it also forms, like Gruber's ligament, a filiform edge, the concavity of

directly with the first fascia, while the external portion encloses these vessels separately, just before the crural arch, and the vessels themselves are immediately situated between these two divisions of the fascia."—*On Regener's*, p. 261, vol. 4.

Where the insertion of the fascia lata into Poyat's ligament ends, it forms what Mr. Ruge of Glasgow called the *falciform process*, the lower part of which is situated in the above ligament, while the lower portion extends further down the thigh. The continuity of the falciform process is directed towards the palm. This well-marked connection is one chief cause, may be said, of the thigh, and rotting it outward, renders the crural arch tense.

The fascia being stretched in front of the pectineus, most of course is directed to the fascia lata. In my opinion, surgeons are very much indebted to Mr. Lawrence for his able explanation of this fact. As for myself, I am careful enough to note, that while I read his clear and concise account of the anatomy of the crural region, I could never bring my accurate notions concerning the relative structure of the femoral vein and fascia of the thigh, from other able and able works, with the exception of those of Blandin and Langenbeck, to represent the accuracy so perfectly furnished. Mr. Lawrence remarks on, however, that the particular femoral hernia, contained in the sheath of the femoral vein, lies under the fascia, p. 270, vol. 4. And he mentions, that "the upper end of the falciform process passes over the upper and outer part of the neck of the femur; it is then folded under the crural arch, and contracts into the first pectineus node. The line just is placed on its upper side, the palm is directly below it; and the upper and outer part is bounded by the falciform edge of Poyat's ligament. It is this part which forms the femoral node."—*On Regener's*, p. 261, vol. 4. While, however, the latter statement is made by this gentleman and others, Mr. Ashley Cooper as positively declares that the sheath is never stretched at Cooper's's ligament, but at the crural arch, just before the sheath leaves the abdomen.—*See Law's*, vol. 2, p. 502. He also mentions, that he has known the structure continue after the division of that ligament, and the pectineus line. The most comprehensive view of this part of the subject taken by Blandin and Langenbeck, I have already explained.

The inner side of the crural ring or canal, as already explained, is connected with the fascia of the transverse muscle. And, according to Langenbeck, below the arch of the fascia lata, which forms the external femoral for the femoral vessels, the outer side of the crural canal is sometimes formed by a continuation of the fascia of the transverse muscle, as he found frequently in both sides of one female subject. In such a case there is a good deal of fit between the fascia lata and the aponeurosis of the transverse muscle, and the two parts are easily separated. Langenbeck adds, however, that the same aponeurosis may arise from a splitting of the layers of the fascia lata. Frequently the front side of the crural ring is so small, that the covering cannot rightly be termed a canal, and it is always shorter than the posterior side. When the outer side exists, it is extended across the lower, over the space between the two femora, and is then connected with the aponeurosis of the pectineus directed from the fascia of the psoas and levator ani muscles. In the anterior and longitudinal of the crural canal, there are some small openings. Doubtless, this structure is referred to by Blandin, when he says, that it is the whole subject the same as before for the femoral vessels is better closed by a net-like web of tendinous fasciculi. The posterior side of the crural canal, or ring, is mainly formed by the part of the fascia of the psoas, which enters its lower opening and joins the aponeurosis of the pectineus muscle. The outer side of the crural lies under the fascia lata, and joins the external and posterior side, where the aponeurosis of the transverse and femoral muscles proceed to the outside of the femoral vein. Langenbeck thinks the opening by which the vein separates passes over the lower side of the falciform process of the fascia lata, might be named the lower aperture of the crural canal.—*See Langenbeck's* *Med. Zeit.* für die Chirurgie, 3-2, p. 125, 127, Nov. München, 1863.

According to Blandin, in femoral hernia, the two apertures of the passage now termed the crural or ce-

tral ring are one-half larger than normal. The outer portion of the sheath of these vessels is perfectly intact, and with it the epigastric artery. The femoral vein no longer lies in the external end of this opening, but rather at the back of the crural pharynx. The external straight edge (the falciform process) of the outer opening is turned more upwards and upwards, and is tightly applied even to the distended femoral vein. In this state of the parts, the lower opening lies as a rule from the middle of the diameter of which, the distal of the inner opening is the passage of the femoral vessels, is transverse. The arch of the femoral vein is that portion of it which lies within the space between the two openings. The posterior side of the crural or passage, now frequently named the crural or femoral ring, is larger than the anterior. In one large femoral hernia, Blandin found it as high as eight inches, but the anterior side of the passage more than one inch in height. The greatest diameter of the lower opening was one inch, five lines, whereas that of the outer one was only one inch, four lines. Most of the posterior part of the neck of the femoral vein, with the hinder side of the canal, lies upon the pectineus muscle, and towards the outer side upon the femoral vein. The neck of the hernia on either side lies in the epigastric line to the posterior side of the psoas. At the outer opening of the passage, the neck is situated at almost a right angle towards the body of the vein; the upper portion of which lies upon Poyat's ligament, but the largest part of it is situated in the compressed lateral of the femoral vein, by which the outer side of the body of the vein, as high as the neck, is separated from the crural vein and level. In the whole subject, when the conditions, named with the cellular substance covering the outer opening of the passage, make great resistance at particular points, the femoral vein, a femoral hernia may be double, or even divided into several portions, a proposition exhibiting which occurrence, is in the anatomical museum at Würzburg.—*See Blandin*, p. 42. Except in a few cases in which the veins had claims of the epigastric artery, no femoral, that vein was very close to the external side of the neck of the femoral vein, much more than it does in an internal hernia.

The use of the femoral hernia of exceedingly narrow at its neck, and while its body begins, it becomes expanded in a pleated form; the use of the following is generally of an oblique pyramidal shape. The body of the use of the femoral hernia makes a right angle with the neck by being drawn forward and upwards. A circumference very necessary to be known in trying to reduce the pain by the tails. Though the tumor formed by the body of the use, is oval and nearly transverse, it is found, when attentively examined, to take the direction of the groin, which extends obliquely downwards and forwards, the outer rather smaller end of the swelling being somewhat higher than the outer.—*See Blandin*, p. 50.

The use of the femoral hernia is said by Mr. A. Cooper to be covered by a kind of membranous expansion, consisting of compressed cellular substance, and named by him the *fascia propria*, which is thus described: "A thin fascia entirely covers the opening through which the femoral vessels, and descends on the posterior part of the psoas. When the hernia, therefore, enters the sheath, it passes that fascia before it, so that the use may be perfectly drawn from its inner side, and the fascia which covers it left distinct. The fascia which forms the crural sheath, and in which are placed the hole or holes for the abdominal vessels, is also protruded upwards, and is joined with the other, so that the two become thus consolidated into one. If a large hernia is examined, the fascia is found to proceed upwards, as far as the edge of the web on the lower side of the crural sheath by which the hernia descends; but in small hernia it passes into the sheath as far as the pectineus, and forms a pouch, from which the femoral vessels are withdrawn, leaving this hernia complete over the hernia."—*On Hernia*, part 2, p. 8. However, Mr. Lawrence has not seen, and is not, on dissection, the above described use of the fascia, and is covered the opening through which the hernia passes, nor does his account refer to covering of the hernia, in ordinary cases, or an elongated protrusion of the sheath for the crural vessels. According to Mr. Ashley Cooper, a weak aponeurosis, which forms the superficial fascia of the head of the

Mr A. Cooper recommends the incision to be directed "obliquely upwards and laterally, at right angles to the crural arch." In consequence of the very deep situation of the posterior edge of the crural arch, and the tight manner in which the posterior sheath is surrounded by the ligament, this elevated position considers that the incision is at great danger of being wounded with the knife, if not made sufficiently oblique. However, the position is to divide the sheath in its anterior part, as in the front margin of the crural arch, directing the edge of the knife upwards and laterally. "If this is not sufficient, he afterwards cuts the thin posterior border of the sheath in the same direction."

After making an incision on the side of a femoral hernia with particular care, on account of its being much thicker than that of a umbilical, and (as might be added) on account of its solid communicating fold, and when having no concern in it covering the incision, Mr. H. remarks: "The structure made upon the epigastric part is very great, as I have already observed; but if the tip of the finger can be introduced within the femoral ring, he finds the umbilical knife, a small incision for the ring is necessary, well be sufficient to cut the point of the ring. If the tip of the finger cannot be introduced at the proper place, a dissection with a long groove must be used instead of the finger; but I prefer the latter. The finger or dissection should not be introduced very near the great vessels, but on the side of the intestine or sacculus which is nearest to the epigastric of the cord path. The incision may then be made directly upwards. The surgeon should take especial care to introduce his finger or dissection within that part where he finds the greatest to be the greatest, which is the species of hernia, or the most interior part of the wound."—(P. 125.)

Cooper's mode is preferable to Mr. H.'s, because, were the operation done on a male, cutting directly upwards would endanger the epigastric cord. In order to obviate this risk, Mr. A. Cooper makes a small incision above Poupart's ligament, and divides the cord out of the way of the knife, with a best probe.

Mr. Lawrence has noticed that an "incision of the most interior part of the sheath is free from all danger, in the ordinary course of the vessels. But that variety, in which the abdominal artery, arising from the epigastric, runs along the inner margin of the sac, seems to preclude us from saying even in this direction." Hesselbach met with a remarkable instance of such irregularity in the origin and course of the abdominal artery in the body of a female, in whom there were two small crural hernie. On the right side, the epigastric and abdominal arteries arose, by a common trunk, from the root of the sheath below Poupart's ligament. They soon separated from one another, the epigastric taking its ordinary course upwards at the outer side of the neck of the hernial sac, while the abdominal made a considerable loop, and ran transversely towards over the artery fibres of the femoral ligament, and continued the anterior and inner side of the neck of the hernia, whence it afterwards proceeded obliquely downwards and laterally, behind the horizontal branch of the coeliac, towards the abdominal foramen.—(Hesselbach, p. 32.) A mode of operating has lately been proposed (*Edin. Medical and Surg. Journal*, vol. 2, p. 235), with a view of avoiding this danger. We are directed to make an incision through the aponeurosis of the external oblique muscle, just above the crural arch, and in a direction parallel to that part; to introduce a director under the sheath from this opening, and to divide the tendon to the right of the director, by means of a curved knife passed along the guide.—(Edin. Med. and Surg. J. vol. 4, p. 126, col. 4.) For reasons which Mr. Lawrence states, this plan is certainly not altogether advisable, and, upon the whole, Hesselbach's method of opening the sheath is the safest. Hesselbach uses a curved probe-pointed bistoury, that runs with its convexity in the direction of the sheath, and with it under the structure, and then its edge is moved upwards, the incision being extended through the upper end of the femoral foramen to the margin of the crural arch.—(*Practical Course*, &c., p. 125.)

Many surgeons, that the abdominal artery may arise from the epigastric, once in twenty-five or thirty subjects. But allowing that it originates more frequently, it then does not always deviate from its usual course along the cord of the sac. Mr A. Cooper says: "In

all cases which I have myself dissected, where this artery entered with crural hernia, the observation has passed into the pelvis, on the party side of the neck of the sac, exiting out of the neck of the danger of the sac."—(On Crural Hernia, p. 31.) Mr. Lawrence concludes, that the comparative number of instances, in which it is found on the opposite side, cannot be more than one in twenty, and consequently, if we admit that the aberrant artery arises from the epigastric once in five times, it would only be falling to be wounded once in a hundred operations.—(P. 122, of 1.)

When the height and course of the epigastric artery differ from what is common, this vessel, as Hesselbach remarks, sometimes passes internally above the horizontal branch of the coeliac, and it ascends towards the rectum itself, and when this variation exists it is a case of femoral hernia, the artery does not pass over the outer side of the neck of the sac, but runs under it, and they run on the inner side. Hesselbach has seen only one instance of this irregularity of the epigastric artery in a female, and never in a male subject.—(Lectures on Surgery, &c., Dr. Lawrence and Schenck, vol. 2, p. 22.)

And lastly, M. Chiquet extended this list for the purpose of collecting the various number of cases, in which the origin and course of the abdominal artery are different from what is most common. He found, that when this artery and the epigastric arise by one common trunk, they sometimes separate from each other above, and rarely below the upper opening of the crural arch. "In the first case, the largest their common trunk, the closer do they lie to Poupart's ligament, and in the lower edge of the upper opening of the abdominal canal. In the second case, the common trunk of these arteries arises within this canal, and the two vessels then again take the above." In 160 bodies, of which 87 were male, and 73 female, the abdominal artery arose on both sides from the epigastric; and only in 36, of which 21 were male, and 15 female, did it arise on one side from the epigastric. In 28, of which 15 were male, and 13 female, the abdominal arose on one side from the epigastric, and on the other from the epigastric. In six bodies, viz. two male and four female, it originated from the crural.—(Arch. Med. and Surg. for November, Paris.)

It is observed by Professor Scarpa that "the round ligament of the uterus, in passing through the abdominal muscles, follows precisely the upper tract of the epigastric cord. It is equally situated behind Poupart's ligament, with the difference, that it does not become so dilated from the internal extremity of this ligament, as the epigastric cord does, because it has not so far to run, in order to get from this ligament to the internal ring, the latter opening being situated lower in the female than the male subject." The round ligament, like the epigastric cord, the common epigastric artery before reaching the ligament ring. And as the crural hernia always begins in the internal and inferior part of the neck of the sac, as well in the male as the female, it follows that, in the first case, the epigastric artery remains in its natural situation, and luxuriantly corresponds to the external side of the neck of the crural hernia; while the epigastric cord is seen, and the round ligament is thrown over the extremity of the first of the neck of the hernial sac. In the operation for the crural hernia, in females, the incision of the neck of the hernial sac and crural arch, when directed upwards towards the femoral vein, cannot wound the epigastric artery, which it is of the most consequence to avoid; but it always divides, either equally, or partially, the round ligament of the uterus, which cannot lead to any dangerous hemorrhage; for, except in the period of pregnancy, the arteries of the round ligament are very small; they are almost obliterated in women advanced in years; and, in general, they are quite capillary in the extremity of the ligament adjoining the ring. Hence, it cannot be surprising that so many crural hernie have been successfully operated upon in women by cutting the hernial sac and crural arch directly upwards, while not a single instance can be cited of such an accident being made in them without mischief, although, in both sexes, the epigastric artery may have been involved in operating by this process.—(Scarpa, Treatise on Hernia, p. 240.)

In operating upon the crural hernia in males, Scarpa recommends us to follow a method, which he calls new, but which, in fact, is the same as that advised by Gim

hernia." "I have found (says Scarpa) that, in fact, the neck of the hernial sac may be divided without danger, by giving to the incision a direction exactly contrary to that which is pronounced in the female subject. After having opened the hernial sac, it is to be drawn outwards by one of its sides sufficiently to allow the introduction of a small dissector between its neck and the stratified ligament, the groove of the stratified ligament being directed towards the internal and inferior angle of the crural arch. A properly guided bistoury, the edge of which is also to be directed downwards towards the point of insertion of Poupart's ligament to the pubis, is to be pushed along the groove. By this means the neck of the hernial sac will be divided in whole length at its internal and inferior end, and Poupart's ligament will be cut close to its attachment to the top of the crural arch. The epigastric artery will certainly be avoided, because it lies upon the opposite side of the hernial sac. As for the spermatic cord, I have demonstrated, that it is situated on the fore part of the neck of the hernial sac; consequently it cannot be divided by an incision made from above downwards, while it is necessarily cut in the ordinary method, since the style is carried from below upwards. In the first case this part may be the more easily avoided as well as kept at some distance from the internal and inferior angle of the crural arch. In fact, it is in this place that it exists, as we have seen, the edge of Poupart's ligament, in order to ascend towards the inguinal ring. "The incision that I propose (says Scarpa) the only has the advantage of dividing open the neck of the hernial sac in whole length, it also divides a part of the insertion of Poupart's ligament into the upper part of the crural arch, a thing that greatly contributes to relax the crural arch, and facilitate the reduction of the hernia; of those at least, which are not obstructed by the sac."—(Scarpa, op. cit. p. 223.)

Although this accurate anatomist and surgeon, at the time when he first published on hernia, was quite unacquainted with the valuable works on the same subject, which had made their appearance in this country, he is equally to be admired, both in his account of the inguinal and crural hernia, here strongly his diagnoses and observations tend to confirm every thing that has recently been pointed upon in modern works, respecting the place where the balano-circus first passes, its passing through a sort of canal before it comes out of the abdominal ring, the advantage of cutting in the crural arch in the internal and inferior angle of Poupart's ligament, or, in other terms, that part of the ligament which was first particularly pointed out by Glisson, as forming the principal part of the strangulation.

Heslinski considers my incision through the outer side of the crural ring safer than one through Glisson's ligament, and safer in women than here. In women, he recommends the cut to be made through the middle of the fore part of the ring, nearly straight forward, or a little inclined inwards, in which mode the epigastric artery cannot be hurt, whereas it lies at the inner or inner side of the neck of the sac. In men, my incision, directed obliquely upwards and inwards, being, almost, he says, on account of the position of the epigastric cord; therefore, in the male subject, he advises cutting the inner side of the opening, that is to say, Glisson's or the female ligament, directly towards the symphysis of the crural arch.—(Gibbs, *des Chirurgie des Femmes et des Maladies*, p. 54.) When the epigastric or crural artery is divided from its usual course, and surrounds the inner side of the neck of the hernia (which variety can never be undertaken as safely, as a wound of the vessel) Glisson remarks as unavoidable.

From the views taken of internal hernia in this article, I consider the unobstructed direction straight to cut Glisson's ligament to be the operation perfectly necessary. For, as Langerbeck has stated, the seat of strangulation may either be in the external opening of the crural canal, or in the opening of the femoral ring, or in the side of this opening, or in its lower opening, where indeed Glisson's ligament is truly collected. When the strangulation is in the first two descriptions, only the vessels have need be cut; but in the third, and the fourth case, the inner considerable edge of the internal opening of the ring, seat of course is divided. In all cases, says Langerbeck, whether the strangulation is caused by the sides or internal opening of the crural

canal, or by an aperture in the first process of the passage, the stricture must be cut inwards, as enclosing the vein in the first description would injure the epigastric artery. When it is posterior, in the opening, that the neck of the hernial sac is somewhat close below, and behind the external edge of the abdominal ring, then the inner opening of the crural canal is to be divided inwards, with the knife directed along the horizontal course of the crural arch, under the external edge of the ring, towards the symphysis of the pubis. If, in such a case, the knife were carried upwards and upwards, that part of Poupart's ligament forming the upper side of the crural canal would be cut, and the spermatic artery injured.—(Nieuw Boek, 2. p. 223.)

Dr. Travers has published some remarks, in favour of employing distention, instead of an incision, in the operation for the stratified crural hernia. He observes, that even when the common trunk of the abdominal and inguinal arteries is short, and somewhat protruded under the first of three arteries, which may be ligated the upper and invariable of the hernia. An operation performed upon a woman, at La Charité de Paris, for a strangulated femoral hernia, the true ligament was divided in Glisson's way by an incision, exactly parallel to the horizontal course of the crural arch, and the external artery was wounded. The patient died eight days after the operation, having been previously attacked by typhus and erysipelas. On dissection, about six ounces of putrid blood were found in the lower cavity of the pelvis, and the iliac artery cut. The vessel arose from the epigastric, ran upwards upper edge of the inner opening of the crural ring, of ring, and then descended along its inner edge, towards the external ring. This communication of the abdominal artery leads Dr. Travers to suggest the following rule: "If, after the hernial sac is opened, the bowel cannot be reduced, the artery springing at the crural canal should be cut directly inwards, in order to produce a considerable relaxation. But, if the incision should not be agreeable, the strangulation being at the lower opening of the canal, then at the point it is to be made to intersect the end of the right through the constriction, a plan will not have answered very often in the practice of serious crural hernia. Should the relaxation be too great, but yet, as the vessel is so exposed, Travers advises the artery to be cut directly drawn inwards and upwards, inwards the canal, with Arnould's testicles, assisted by the introduction of the finger, or with two hands. When this plan fails, he recommends Scarpa's process of dividing the anterior edge of Poupart's ligament with a pair of blunt-pointed scissors, and that the use of Arnould's instrument again.—(See *Archiv. Med. et Chirurg. pour les Écoles de Médecine*, t. 5, p. 2.) The consideration, however, which will ever prevail the common adoption of Dr. Travers's suggestion, is, that fifty times more lives would be lost by the method done to the protruded bowels by the female production of the finger and thumb, than by incising down the obstructed or inguinal artery, with the course of the finger is irregular.

Of late years, a kind of considerable interest has been awakened in relation to the crural hernia; viz. the possibility of the bowels by the method of the operation, and the sharp edge of Poupart's ligament, is a point, that either a permanent contraction of the artery, alteration of the arterial and venous state, or even that of the veins (the last may occur, followed by final extravasation, after the reduction of the hernia by the operation)—(Glisson, in *Med. Chir. Praxis*, vol. 2, p. 224; *Abhandl. ch. cit.* vol. 2; *Ann. Chir.* p. 117, 118.) Hence, the latter gentleman is an advocate for gently drawing out the bowels, after inserting a fluid structure; if it is removed he would be exposed to perfect loss of the vein, he advises its reduction; but, in the opposite case, he directs to be left out of the abdomen, rather than that the patient should be exposed to the danger of effusion into the abdomen.—(P. 441.)

CONGENITAL HERNIA.

Before the beginning of the sixth month of the fetal state, the tunica is situated near the kidney, where it receives a covering from the peritoneum, and into the after abdominal space. Between the beginning of the sixth month, and end of the seventh, the tunica has either descended as low as just above the umbilicus,

small ring, or else by passing through it, or around a little below it.—(Frisberg, *Ann. Roy. Acad. Med.*, 1788.) When the tunica passes through the abdominal ring into the scrotum, it is supposed to form a protrusion of the peritoneum, which afterwards contracts the tunica vaginalis, while the peritoneal investment, which was given to the tunica in the abdomen, is closely adherent to this body, and forms what is termed the tunica albuginea.

After the descent of the tunica into the scrotum, the communication between the cavity of the tunica vaginalis and that of the abdomen becomes obliterated, which latter event is usually effected before birth, sometimes not till afterward, and, as a few authors, even as late as the adult state.

In the congenital hernia, the protruded viscera are enclosed in tunica vaginalis, in contact with the testis, having descended into this position before the closure of the communication with the abdomen. Of course, the tunica vaginalis lies in the hernial sac. The nature of this case was not understood, before it was elucidated by Hager in 1755, and the two Hesters in 1762 and 1764.—(See Hunter's *Med. Comment.*, *Haller's Opuscula Pathologica et Opera Medica*, t. 3.) Many particulars, relative to the origin and formation of this hernia, having been given in the fifth edition of the *First Lines of Surgery*, I shall not here repeat them. Before the peritoneum now named, surgeons supposed the circumstance of the contents of the hernia and tunica being in contact, as the tunica having made their way, by absorption, through the tunica vaginalis, from the ordinary internal sac of a hydrocele. The allusion, indeed, is perfectly true; but, in point of their doctrine, that some tunica are attended with a protrusion of the peritoneum.—(See Abernethy's *Lectures*.)

From the foregoing, the right surgeon, that this hernia always existed in the time of birth. The protrusion, however, seldom occurs till after this period, on the expansion of the canal leading either of hernia or sperm. It does not uncommonly happen at some months after birth, and, is coming sometimes, not till a late period. Mr. Hey's case, in which a hernia congenita was first observed, in a young man, aged sixteen, whose right testis had, a little while before the attack of his disease, descended from the scrotum.—Is the generally of cases which actually take place when the tunica descends into the scrotum before birth, the case may be referred to the tunica having contracted an adhesion to a piece of membrane, or membrane, as the passage in the ring. In an infant, whilst a few days after birth, Withers found one tunica, which had not passed the ring, adhering by means of a few slender filaments, to the osseous, just above this aperture. Dependent adhesion of the tunica to the adjacent viscera, instead of leading to the formation of a congenital hernia, only prevent the descent of the hernial organ. Cooper examined the body of an old man, in which the testis lay on the pectus and adhesion tunica, connected to the sigmoid flexure of the colon, while an inguinal hernia existed on the same side.—(Becker's, *loc. cit.* p. 24.) Sometimes protrusion at all happens, even though the communication between the tunica vaginalis and abdomen remains open in the adult subject, as is particularly illustrated in a case recorded by Hesselbach, where each communication existed on each side in a man thirty-eight years of age, without any hernia.—(Med. Clin. *Review*, 1815, p. 100. Also, *J. Cooper*, in *Lancet*, vol. 2, p. 672.)

The appearance of a hernia is very early noticed. Mr. Pott observes, will always think it probable that it is of this kind; but he was not correct in assuming, that it is the first thing that he notices for suppurating his rupture on the day out, but his having been attended with it from his infancy, and that there is no external mark of character whereby it can be certainly distinguished from one sustained in a common hernial sac. This supposition is erroneous, because as the hernia organ is attended with an responsibility of feeling the testis, which part in the common hernia is always the distinguishable body the feeling of the hernial sac.—The hernia congenita, when communicating, "ought, like all other hernia, to remain, when reduced, and constantly keep up a pain, swelling, and when attended with symptoms of inflammation, it requires the same discharge, treatment as the common hernia."

Mr. Pott observes, that "in very young children, a piece of intestine, or stomach, may get partly let down in the bag, while the rest is still in the groin, or even within the abdomen. In this case, the suppuration of a tumor would be highly improper; for, in the latter, it might prevent the descent of the tunica from the belly into the scrotum; in the former, a more conveniently tense and injure it, give a great deal of unnecessary pain, and give proof of no real cure. Such hardages, therefore, ought never to be caught into a rupture in an infant, unless the testis can be fully felt in the scrotum after the gut is cut it is reduced, and otherwise can be so felt, a tumor can never be put on too soon." This is also the advice delivered by Sir A. Cooper.

As Mr. Pott has explained, an old rupture, originally congenital, is subject to a rupture made by one the testis, as well as to that produced by the abdominal ring, or, as might have been added, to that caused by the linear opening of the inguinal canal.

The gut is reduced several times, but in the end and in the latter. "I have seen (says he), such structure made by the gut of one of these hernia, as produced all those bad symptoms which render the operation necessary; and I have seen with very different structures, it was on each instance from each other, in the body of a dead boy, about fifteen, one of which would the intestine so thick that I could not disengage it without dividing the sac."

In this kind of hernia I have also very frequently found adhesions and adhesions of the parts to each other than in the common case; but there is one kind of congenital sometimes met with in the congenital hernia, which can never be fixed in that which is in a common hernial sac, and which may furnish all the difficulty of its operation or solution; I mean that of its adhesion with the tunica.

If a large quantity of fluid should be collected in the sac of a congenital hernia, and by adhesion and compression of the parts within the tunica into it from the abdomen should be finally closed, (a case which I have twice seen,) the tightness of the tunic, the difficulty of disengaging the testis, and the fluctuation of the fluid, may common it to be mistaken for a common hydrocele; and it will attend to other circumstances, but trusting myself to the test and look of the tumor, I presume to be mostly true, it may create a great deal of trouble, and possibly do fatal mischief.—(Pott, vol. 2.)

Mr. Pott also believed, that congenital hernia, or those in a particular case, are generally gradually formed, that is, they become inguinal, and by degrees become scrotal; but that the inguinal are seldom accompanied by the patient to have been in the groin only. As the tunica vaginalis is thicker than the peritoneum, one portion of a congenital hernia may not so much felt as those of a common rupture. In children the tunica generally communicates only, the overture can be felt; in these sufficiently long externally to protrude.

The sac of a congenital hernia, especially when the one is congenital, is every where equally tense. (Hesselbach, p. 26,) and below it the tunica cannot be felt.

The reader need not conclude, however, from the above account, that every rupture in children is congenital. Mr. Lavern is indebted a case of strangulated hydrocele, which took place in an infant only twenty months old.—(J. G. Med. J.,

The common inguinal hernia, which first protrudes at the lower opening of the inguinal canal, and which has the tunica arising on the inner part of its neck, has been termed by Hesselbach external; while the less common instance, in which the tunica has its origin directly on the apertures of the transverse and internal oblique muscles, and goes directly on to the abdominal ring, having the tunica arising on the outer side of the neck of the sac, is distinguished by the epithet internal.—(Cooper, *Chir. Med.*, 1826, p. 600. Also *Cooper's Lectures*, 1826, p. 100.)

The internal congenital hernia, as collected above, is divided into external and internal; it is evident that it might always be external, above the neck of the tunica, and might correspond to the part, at which the spermatic cord passes under the tunica of the hydrocele muscle. As for other circumstances, the tunica vaginalis has in its whole extent to the same

surface to the back of a common vegetable leaflet. Now this, it passing constantly through the inguinal canal from one side to the other, passing upon the anterior surface of the spermatic cord. Consequently it passes between the semitendinosus and the tubercle above of the oblique foramen, and the muscular belly of the spermatic muscle.—See Whistler, *Opus. Comment.* about p. 24. After coming out of the ring, as it is always found to do, spermatic cord, it is enclosed by the musculo and aponeurotic sheath of the spermatic funicle, which accompanies it to the bottom of the scrotum. Hence the tunica vaginalis, enclosing the displaced vessel, enters the inguinal canal on the outside of the point at which the spermatic cord crosses the epigastric artery. It is evident, then, as it follows along the direction of the cord it must also cross the artery, and remove it from the situation on the other side of the ring according to the position already explained in speaking of the common inguinal hernia. Hence the displacement of the epigastric artery constantly happens in the inguinal canal, just as it does in the ordinary external inguinal hernia.

But these two species of inguinal hernia have some analogy in each other, as is proved by the particulars mentioned there, yet they present some remarkable differences. 1. The common inguinal hernia, whether strangulated or external, when it extends into the scrotum, cannot descend beyond the point at which the spermatic vessels enter the testis. The other cellular difference of the spermatic cord remains. Thus the hernial sac must also necessarily herniate. In the contrary, in the common hernia, the vessels may descend lower than the testis, with which they are in contact, and descend; and at length, they occupy the situation of the spermatic vessels, which is then pushed downwards and backwards. 2. In the case of a common hernia, the descent of the vessels from the groin to the scrotum, completely takes place at a very short time, and in some moments particularly. It is much slower and more gradual in the ordinary inguinal hernia. The reason of this difference is very plain. In the first case, the descent of the vessels, and the formation of the tunica vaginalis, take speed and prepared the way, which the vessels again follow in forming a protrusion; while, in the second, the hernial sac cannot descend into the scrotum, but by gradually displacing the layers of the cellular envelope which join it to the surrounding part. This fact is so generally known, that experienced practitioners consider the protrusion with which the vessels have descended from the groin to the bottom of the scrotum, as a characteristic sign of a "scrotal inguinal hernia!"—[See, *Treatise on Hernia*, p. 72, &c.; *Monro's*, p. 35, Part, &c.]

In the hernia vaginalis the spermatic artery and vein are sometimes on one side of it, and the epigastric behind it. A protrusion, exhibiting this situation of the cord may be seen in the museum of St. Thomas's Hospital.

If circumstances will admit of a man being applied and worn in cases of scrotal hernia, of course success there will be a considerable chance of a radical cure being effected, in consequence of the natural proximity of the spermatic between the abdomen and tunica vaginalis to become closed.

In the operation the surgeon has to lay open the tunica vaginalis, instead of a common hernial sac. Now, as Dr. Aclay Cooper judiciously recommends, this operation should not be performed during life, but because a sufficiency of it should always be left to render the vessels, and also, because the spermatic artery and vein are situated obliquely on the first and larger portion of the inguinal. He therefore thrusts three fingers of the lower part of the tunica vaginalis to be left undivided.—See Cooper, vol. 2, p. 175. The incision is to be directed on the same principle as that of an inguinal hernia, and it is in the same position. As, in a case of inguinal hernia, the point is a ways protruded on the outside of the spermatic artery, the structure may be safely divided towards the flum, as well as directly afterwards.—See Cooper on Hernia, p. 307, &c. 4. According to Sir Astley Cooper, the operation is possibly done in such and a half from the abdominal ring, except in three cases, when it is nearer to it. The parts having been reduced together, and retained in by means of one or two external and sticking

plaster, which is much preferable to the old plan of applying bandages to the outside and inside of the tunica vaginalis, so as to hold the part by one grasping power.

A new species of hernia, however, has described by the late Mr. Hey, in which a portion is protruded behind the tunica vaginalis, and is contained in the tunica vaginalis. It arises from the parts being protruded after the communication between the abdomen and tunica vaginalis is closed, so that the spermatic is confined down along with the tunica, and forms a hernial sac within the tunica vaginalis. It is sometimes also, that such a hernia can only be produced in the original tunica vaginalis remains, in the form of a loop, as high as the abdominal ring. Operation should be made of the possibility of having a sac to drive into during open the tunica vaginalis.—See Hey, *Medical Obs.* p. 224; Dr. Rutledge, in *Ann. Med. Juris*, No. 67, p. 484; and Sir J. Cooper's *Work on Inguinal Hernia*, p. 224.

INTERNAL HERNIA, OR ECTOPYCAE.

The exemplar, or internal inguinal hernia, is so called from its situation, and has the same basis as the external, contains a portion of intestine, or omentum, or both. In old medical writers the quantity of omentum is sometimes very great. Mr. Hunter says, that he found them also a small portion of testis in one of them, with about a third part of the omentum, not adhering together. Mr. Guy and Dr. Keene found the liver in the sac of strangulated hernia; and Bichat says that he observed. He observes also the contents, they are originally contained in the sac formed by the protrusion of the membrane. In recent and small herniae this sac is very easily felt in an old and large one, it is broken through by the heat of the finger, by the pressure and weight of the contents, and is not always to be distinguished, until the hernial ring it has by some been broken, when the kind of rupture has a hernial ring as well.

Infants are very subject to this disease, it is most frequent from the expansion of the uterus; but in general they pulled out of it so they escape, or are easily cured by means of a poultice. It is of still more consequence to get this disorder cured in females, than in males, for if it remains, they are become infertile and pregnant, may be produced as much as possible, for at this time of life, before the too great distention of the uterus, or from the guarded motion when the parts are upon the weak, during position it is often very troublesome, but in delivery, if the contents have contracted in albumen, they will often strangle, and may be kept in this way by a proper bandage.

If such bandage was always put on as it is, and worn constantly, the disease might be cured of any within moderate bounds, and some of the very best consequences which often attend hernia prevented. The woman who has the smallest degree of it, and who, from her age and situation, left certain children after its appearance, should be particularly careful to keep it contained.

In some instances of the sac it is large, and is much easily reducible; in others they are small, and in some absolutely irreducible. Of the latter kind who have been operated for, value for a proper bandage, and given little or no trouble. They are not different with this disorder, who are observed in life, and in whom it is large, and generally subject to inflammation, and, if the inguinal canal is at all enlarged, to very troublesome swellings. Others, however, are often supposed to labour under a tumour when they really do not. It therefore becomes such a task to find out, to keep the tube as clean and free as possible, and neither to eat or drink any thing which may be dangerous to that part.—See on Hernia, vol. 2.

Authors who have published since the time of this celebrated surgeon, have not added much to our stock of information with respect to this disease, the exception is. The writings of Sir A. Cooper, *Opera*, *Treatise on Hernia*, p. 327; and all the other modern writers confirm the fact described by Port, that in the inguinal inguinal there is a hernial sac, just as in a common inguinal or scrotal. Every one acquainted with anatomy knows, that behind the opening in the linea alba at the umbilicus, the peritoneum is complete, and consequently

total protrude along with the viscera in cases of strangulation. In the early days, about thirty years ago, it was not a deficiency of the ring, the weakness of the ring partially absorbed in ligament, so as to allow the protrusion of the contents, and therefore, from this cause, a hernia occurred. Similar appearances, however, in the expected, produce give rise to the rupture in infancy mentioned by Blandin. De la Paire, Gossageot, and J. L. Petit, that, in the umbilical hernia, the peritoneum was always ruptured, and there was no hernial sac. According to Ricard, early infancy is more subject to the umbilical hernia, directly so called, in which the peritoneum protrudes through the ring; while in the later periods of life we never find it with any degree of rupture, or such as occur in the rupture of the umbilicus. (Harcourt's *Chir. de l'Enfant*, p. 2, p. 215.)

Butler is of the opinion, and the explanation is also covered by a more scientific explanation, consisting of condensed cellular substance. In operating, however, a hernia should always cut with great caution; for the peritoneum will hernial out in front of the incision and immediately adhere; and, moreover, in large cases, when an abstraction of part of the sac has been raised by the pressure of the abdomen, they are even found adhered to the integuments.

Urgent hernia, and discolored and complete strangulation, are particularly liable to be misdiagnosed. In such cases, when there is fulgidity in the eye, considerable general symptoms. The pressure on each side of the tumor is observed to be particularly firm, and the skin is discolored, but the heat of the tumor is not sufficiently pronounced, and upon the surface has been found no rupture in the wall. (See *Lancet* on *Hernia*, p. 24, 1850, &c.)

In the case of hernia, the symptoms are such by the position occurring in the last case. Let us now consider the inguinal hernia, the more particular form in which it has been noticed by the late writers.

INGUINAL HERNIAL HERNIA.

In children, but not with about two years of this kind usually for the space of eighteen years, and they strictly observe the epigastric region, as they appear at birth. The fluid is in a sort of bag, containing some of the viscera, which pass out of the abdomen through an opening in the thickness of the ring. The opening is self-sealed with skin, so that the contents of the hernia can be seen through the thin distended covering of the cord. The disease is owing to a congenital deficiency in the abdominal muscles, and the hope of cure will be regulated by the size of the excision, and quantity of viscera protruded.

The plan of more proposed recent of the employment of a ligature, or of a bandage. The latter is more preferable, and was proposed by Mr. Hey, as follows: having reduced the intestine, he desired an assistant to hold the fluid compressed sufficiently over the abdominal ring to keep the bowel from returning into the hernial sac.

"I procured (says he) some plaster spread upon leather, cut into circular pieces, and laid upon one another in a circular form. This composed I placed upon the hernia, after I had brought the skin on each side of the opening into contact, and had laid one of the lips a little over the other. I then put round the child's abdomen a flannel belt; and placed upon the neck a thick, elastic, quilted pad, firm as a brick, two inches from one extremity of the belt."

"The bandage kept the intestine securely until the abdomen, and was applied immediately. The next was separated about a week after birth, and at the expiration of a fortnight from that time the operation at the umbilicus was performed, and the crying of the child, when the bandage was removed, did not excite the least pain. I thought it proper, however, to continue the use of the bandage a little while longer. A small excision, five lines deep, produced, when the fluid had dropped off, about half an inch from the ligament of that depression which the ring forms. A piece of the ligament with great care was cut out, and secured by the pressure of the bandage, brought in a complete cicatrization." (A. 177.)

This gentleman has referred another example, in which the ligature was quite successful, and is

dated, the one having been in delivery. The parts were reduced; but the child died.—(See also *Ed. J. Pract. & State Medicine*, 1844, under other diseases of the umbilicus. August 1851, [See p. 38].)

INGUINAL HERNIA IN CHILDREN.

The inguinal hernia, which is sometimes formed in the fetus, from causes difficult of explanation, takes place in other instances, at the moment of delivery; and thus, as Schöler remarks, should it be tied by mistake with one thread, death would be the consequence. Most frequently, however, it is not till the second, third, or fourth month after birth that the disease occurs; and the reasons are various. In the first years of life, if the viscera are attacked with this hernia, because affected at the periods just mentioned.

The children, with open, torn ligament in contrast, so as to allow the viscera, which have found an opening capable of protruding a protrusion of the viscera. Sometimes, however, the opening exists of the child, and the viscera protrude the opening, and then the closure of the covering of the ring is prevented. By degrees, the unobstructed opening becomes more and more dilated, the protrusion of protruded bowel increases, and the viscera, which, from being of fetal size at first, at length attain the size of an egg, or like water, and pressure itself with all the elastic force of a hernia.

The protrusion of a portion of intestine and contents in the hernia, keeps the umbilical open, and sometimes a partial weakness which it has to close. Such weakness, however, being sometimes superior to the resistance of the protruded parts, forces them back into the abdomen, and thus the opening through which they passed, and then the spontaneous cure of the umbilical hernia in children is accomplished. Two circumstances of this fact are related by Ricard.—(Harcourt's *Chir. de l'Enfant*, l. 2, p. 215.)

Nature, however, does not effect every such cure, and when the cure is left to her alone, she not only fails in securing about a useful cure, but gradually renders it impossible. In short, the propensity of the opening to close disappears, and is lost in the subject grows older.

Thus, an umbilical hernia of children seems to be essentially different from that of adults, in the tendency of the opening to contract. Hence the rule of effecting a radical cure in children, and the direct upon responsibility of doing so in adults. In the former, it is enough to keep the intestine from protruding, and the opening becomes of itself obliterated; in the latter, the opening always remains, whether the hernia continues to it or not. This independence of the opening to contract in the adult, also, depends upon the protrusion not being through the umbilical ring itself, but through a fissure in the vicinity of it, not united with the same natural tendency to close, which the umbilical possesses in young subjects. In fact, it would appear from the observations of Scarpa, that unless a given pressure has had the protrusion from hernia, it never occurs exactly through the umbilical ring itself.

The means of curing the umbilical hernia of children, are compression and the ligature. The former is the most common; the latter the most ancient treatment, as it is mentioned by Celsus. The object of both is the same, viz. to prevent the lodgment of the protruded viscera in the opening of the intestines, and thus facilitate the approximation of its sides. To accomplish this end, the ligature encircles the hernial sac, and the skin pulled before it; and by the action of the cure, a cicatrix is produced, which secures the protrusion of the viscera. At the same time, the skin of the hernia, when their natural tendency, compresses them the tendency in opening, in the period of the abdomen, hinders the protrusion of the bowels, and keeps these parts from meeting the contraction of the ring. Ricard remarks, that through compression, as well as by the ligature, during the great length of time in which it is necessary. The ligature (the skin) produces permanent gain; but it is not at all violent, and it effects in a few days, what compression, when successful, accomplishes in several months. In such plan, long and continued attention is requisite, and if its employment be only for a short time, the effect the previous effect becomes almost destroyed. The other method accomplishes its object with

for those accidents, enjoyed, indeed, the greatest perfect health in every respect.

"Whenever persons are obliged for trying the method herein, it is evident that the patient can only be considered as far as a man, and on this side of the operation, long as the weakness, whatever it be, exists, and the instruments must always remain placed and related to a certain point, as the time and the circumstances of this operation. Also, after the operation of the strangulated person, take necessarily measures under the cloth, a person on the lateral side, and in the lying instrument which involved it, and as the chronic itself is not supposed without distress to make the impulses of the exterior, which tend to separate themselves from the remains of the hernia, and the hernia, some or later happens, and in a short time becomes larger than it was before the operation. If the subject is a little girl, it may be apprehended that the first pregnancy will cause a recurrence of the hernia; so, it is happy that during pregnancy and maternal remains of the weakness is considerably diminished, and much disposed to give way."

Scarpa then remarks, that "after the operation of the hernia, there always remains between the abdominal ring of the hernia and the adhesions a small cavity formed by the neck of the hernial sac, a cavity into which the viscera begin to infiltrate themselves after the operation, as so to kindle the complete consumption of the ganglionic sac. The demonstration of what here is intended is, it seems necessary, to be based on the method of operating on the inguinal hernia, not in a strangulated state, by the separation of the hernial sac and epineurial coat. Many of the hernia operated upon by this method, proceed from subject to relapse, because, in this proceeding, the clitoris was not sufficiently firm to resist the impulses of the viscera, which entered the remains of the hernial sac. In the same manner, after the operation performed for the strangulated inguinal hernia, although the clitoris is found very firm the ring, there is no prudent surgeon who does not advise the patient to wear a bandage the rest of his life, observation having proved that the hernia is still liable to recur."

"The existence of hernial sacs, in youth, that compress above is an extremely dangerous method of relieving the mechanical hernia of young persons. It is attended with serious and, provided it is associated with the inguinal hernia, it is hardly ever necessary to continue it longer than two or three months for the purpose of relieving a compression. On the other side, if it be actually proved by all that I have been observing, that the ligature never admits of a perfect cure without compression, it is probable, that if it cannot be so advantageously for the relief of the hernia, some advantage cannot be derived from it. It may be said, that, in general, it does not shorten the treatment; so, in the least momentous cases, the subject may be less troubled by less than a month, and, therefore, make the cure critical, instead of compression must afford no benefit, by reason of a hernia, the viscera larger. It has already been stated, that three months are commonly sufficient for achieving a radical cure by the more employment of a compressive bandage."—(Scarpa, *Treatise on Hernia*, p. 344-349.)

M. Girard published a dissertation on the medical hernia of children, which was read to the Medical Society of Lyons in May, 1811, and the object of which was to recommend compression as an efficient means of cure. The arguments used were very flimsy in those advanced by Girard. In the course of the discussion, M. Carles observed, that he had seen many children operated upon by Denon, who were cured of their hernia.—(Scarpa, *Opusculum*, p. 344, 345, 346.)

The subject now proposed takes up by the Medical Society of Paris, and the result of the debate was, that the employment of the ligature must be rejected. 1. Because the cure of inguinal hernia is often accomplished by nature alone. 2. Because compression, either above or below, causes, sometimes, serious accidents. 3. Because the operation of the hernia does away the means, in regard to being painful, and sometimes dangerous, if unfortunately a piece of intestine should happen to be included in the hernia. It was recommended in general, except with the assistance of compression, of being sometimes necessary, par-

ties, as Denon himself gives the instance of. An instance of M. Carles, the insufficiency of his ligature was long afterwards acknowledged by Denon, *loc. cit.*

The treatment by compression is generally preferred by English surgeons.

INGUINAL HERNIA IS AVOIDED BY LIGATURE.

This case is well treated by the principles common to all surgery. When operating, the patient should be kept upon a bandage or truss, which puts, however, upon a position, which is best of a truss. Mr. Key has described some very good reasons for the operation, which are applicable to children, when compression is performed, as well as to adult subjects. These are recorded by the late Mr. Mahon, an experienced anatomist at Leeds.

"It consists of two pieces of this elastic band, which encircle the sides of the abdomen and loosely fasten behind. At these extremities carefully they form exactly as one ring, to one side of which is fastened a spring of steel of the form represented. At the end of this spring is placed the point of a thin piece of wood, which is placed in every position of the body, and is thereby retained constantly within the abdomen. A piece of elastic or iron is fastened to each side of the metal ring, having a continued loop at its ends, through which a piece of tape is drawn, that may be tied behind the body. This contrivance helps to preserve the abdominal steady in its proper situation."—(Practical Observations on Surgery, p. 211.) And, in the second edition of the preceding work, Scarpa gives the description of the operation of Mr. Mahon, of Leeds; but, no name is given of this instrument, with an engraving in the last edition of the *First Essay on Surgery*, it is not now given the description.

When the compression is immediate and large, the truss must be supported with bandages.

It is observed by Scarpa, that the inguinal hernia, and those of the femoral vein, are less subject to be strangulated than the inguinal and femoral hernia; but that, when they are unfortunately affected with strangulation, the cure was less easy, and the operation more on more rapidly, than in every other species of hernia. If the operation be performed, the event is frequently unfavorable, because it is generally done too late. This practical fact is proved by the experience of the most celebrated surgeons of every age.—"It is certain," says Bland, "you do not operate it as you should, and it is not so favorable."—(Essays on Operations, p. 98, et seq., and *Journal de La Faculté*.) The same adds, that they who have the misfortune to be affected with an inguinal hernia, should rather dispose with their shirt, than a bandage. He then nearly the same thing.—(Practical Observations, p. 211, 212.)

When the operation above is strangulated in the inguinal, or hernia of the femoral vein, observation proves that the operations are not so favorable than when the hernia is also strangulated. There is this difference, however, that when the operation above is strangulated, very serious accidents, and, if entering should likewise take place, it is less frequent and violent than when the femoral itself is strangulated. In the first case, the accident hardly ever extends beyond the protrusion of the stomach in, or death, the reason why the strangulation of the operation in the inguinal hernia occasions the more intense symptoms of sympathetic irritation than the strangulation of the same vessel in the inguinal or femoral hernia.

Then the operation is not only always necessary, but usually required. It is not materially different from that which is performed by strangulated inguinal and femoral hernia; but, in general, it demands greater compression on account of the contraction, it is a more tedious, which frequently arises between the inguinal and femoral sacs, and after the adhesions which often grow between the latter part and the operation which it contains. The situation of the fundus, which is frequently exposed by, and enveloped in, the operation, is another circumstance directing correct attention.—(Scarpa, *Treatise on Hernia*, p. 351, 352.)

Mr. Ford, in his book on the operation in cases of cancer, observes, "The medical, and the surgical way, because the nature of the operation, with the

[illegible]

IBERIA: CHERRE, *Scopas* Desv., *Europae* (coll.) There are two principal kinds of Iberia (cherre); one presents itself in young infants; before the ossification of the skull is completed, the ether takes possession of the dissection of a part of the skull by the operation of the trephine, artificial violence, or otherwise.

The magisterial beauty of the illustrations, however, is in two very different forms: in one, it is created by the seals; in the other, the corresponding image results if the head and sometimes even the foot prints, are inked.

The cutaneous exfoliations, seen in this case, were more extensive, seemed to originate from the imperfect ossification of the skull, especially in the situation of the frontalis and occiput. This view is characterized by a well-marked, of an equal sized shape, which is attended with a pulsation corresponding to that of the pulse; it yields and disappears under pressure, offers no alteration in the colour of the skin, and is circumscribed by the margin of the defective portion of the skull. (Forrest, in *Ann. de l'Hôp. de Chir.* t. 12, 1804, p. 302.) In general, the morbid facies are not affected; and the mind is unimpaired, in which a patient just such a horrid boy has lived many years, exhibiting his facies from early being born impaired during the whole of that period. (*ibid.* p. 3, v. 1, p. 302.)

It is naturally well understood, that the compensation justice would, which arises from the isoeconomic condition of the skill, and is required by the public, ought to be treated by the application of economic, yet labor-saving, means. M. Hoffmann is recommended to the Royal Academy of Surgery in France on account of the good effects of this treatment, which reduces the size of the tumor, and accomplishes a perfect cure.

mean as the construction is completed. M. Saltenevskii, a plover of this short head, properly covered with soft down, under the chicks' caps, to which it was suited in a suitable situation, and the degree of pressure was increased, or lessened, according to circumstances required, by tightening or loosening the cap—(Ost. cit. p. 202, t. 12, of Mus.)

The experience of Gallows also confirms the fact that human conduct, when of a selfless type, may be moved by the foregoing method, the quality becoming gradually altered. That is, able, that large majority of his presence, especially when situated about the subject, actually admit of any number of relief, except the employment of more conventional to protect them from external injury. (Gallows, *System*, *Key*, *Hebrew*, vol. 2, p. 312, 314, c. 1280.)

When the infection of the uterus is chronic, it is late, the discharge, as well as the ovaritis, is liable to persistence. In 1892, two such cases occurred at Paris. In one, Professor Lannelongue removed the uterus for carcinoma, and encountered an abscess of its cervical orifice. After taking note of the anatomy acquired, his proceedings were stopped by him, seeing the white stony mass of the new cancer, and that the abscess came out of its position in the cervical horn. Today after the operation the abscess was found with larger pain in the fund, had a hard wall, protrusion of strength, vomiting, &c., and died in the course of a week. On dissection, a part of the fundus, and an abscess of two two inches in the thickness, alone as large as a nut, were found in the protruded end of the dark matter. Several abscesses were also discovered in the substance of the cervix. The other example (2) was the consequence of M. Hugué, principal surgeon to the Hôpital des Epaves. Upon the death of the child, the abscess extended almost apically—(Chirurg. Néonatal, Clin. 2, p. 289, of 4).

Both facts should reach the airport to be particularly distressing is re-evaluating the value of insurance about the back part of the head, before the ventral, to increase their survival.

The second kind of compound encephalocoele is that in which not only large portions of the cranium, but also more or less of the integuments of the head, are deficient. It is usually to be regarded as a malformation, rather than a disease, and, indeed, in most instances, the infants live wellborn. The case mentioned consists of the presence of most of the brain through the inferior and posterior foramina, so that the child is born with a large opening, the back of which, hanging down over the posterior part of the neck. Several specimens of these malformations, taken from infants born in the Hospice de la Metairie, are preserved in the museum of the Faculty de Médecine at Paris.—(*Archives, Néerog. Chir.* t. 2, p. 216, col. 4.) In the year 1816, a remarkable case of this kind, with description of congenital *Sinus cystos*, was published by Dr. Barrois. "The whole of the forehead, vertex, and a great part of the occiput, were deficient, and in lieu of them, a substance composed of a lightish fleshy colour, and of the consistency of wax, except that it was proportionably broader. From the deficiency of bone, the eyes appeared to project much more than usual. The child lived six days without either taking sustenance, or having any excrement." On dissection, the scalp, the os frontis, the parietal, and a small part of the occipital bones, were wanting. Through the parietis, which three leaves were deficient, the cerebrius projected, exhibiting the usual *gyrificationes*. It was covered with the pia mater; none of a milky colour; appeared to be more vascular than the pia mater usually is; and the edge of the scalp adhered to the neck of the tumour. The cerebrius was not taller than one-fourth of an inch high; on the posterior part of the os occipitis was much more in the form of a tumour than usual. The child was destitute of the power of voluntary motion, and after the treatment applied, he stopped.—(*Ibid.* *Chir. Franç.* vol. 4, p. 52.)

The most interesting species of *hemia* contribute the paradoxical, in that, which sometimes occurs after the removal of a portion of the shell by the coralline, or the destruction of part of it by the stone. You can examples of this disease are recorded in the *Mémoires* of the French Academy of Surgery, and I have myself seen such instances of it. Although the case has

attracted considerable notice, recent surgeons are in favor of performing similar operations concerning the excision of the lamina.

In one example, recorded by Mr. Abernethy, the hernia rendered acute on the fourth day after birth, and was as large as a pigeon's egg. The pia mater, covering it, was inflamed, and a white serum was discharged at the sides of the swelling, near beneath the dura mater. On the seventh day, the patient was as large as a hen's egg, and still ready to burst. The next day the work day. On examination, the swelling was found still larger, and of a dark color, with an irregular protruded surface. The appearance was owing to congested blood, which adhered to its surface, as the part had been so much that the patient's cap was rendered quite stiff with blood. The pia mater was in general much inflamed, and, as well as the dura mater, was detached at the place of the hernia. The deeper part of the swelling seemed to consist of coagulated blood, and it was found to originate about an inch below the surface of the brain.

Mr. Abernethy explains the formation of the disease as follows: "In consequence of the brain being situated so low beneath the surface, disease of the vessels and consequent effusion of the blood had ensued: the effusion was, for a time, restrained by the expansion of the brain and its contents; but, those gradually yielding to the expansive force exerted from within, and at last giving way altogether, the fluid blood coagulated and condensed upon the surface of the brain." An organized fungus can hardly be produced so rapidly as these tumors are formed.—*See Journal of the Medical and Surgical Review, vol. 2, p. 36.*

On the contrary, Mr. C. Rich declares, that the swelling is vascular and organized.—(*Operative Surgery, vol. 1.*)

Dr. John Thomson also entertains a different opinion from that of Mr. Abernethy, respecting the mode in which these tumors are formed; but I question whether he may not have confounded with the disease now under consideration, fungus tumors of the dura mater. At least, several instances to which he alludes, as a reason for his sentiment respecting their mode of formation, must have been the fungus as well described by H. Joubert.—(*See Brain Matter.*) The reader, however, must judge the himself from the following passage:—"It is a considerable number of those who had the cranium severely injured, or fractured by some other cause (Mr. Thomson), fungus grows thick place through the openings which had been made at that by the ball, or afterwards by the surgeon. These growths, I am inclined to believe, are the consequence of a solution of the substance of the brain, and of the exposure that border it, which gives rise to the formation of a new organized substance, different in its texture from brain; and also, as some late writers make endeavor to persuade us, highly putrescent of the brain, resulting from the removal of the natural substance, which is replaced by the dura mater and contents. I have known instances of inflammation, similar to these growths, forming on the surface of the brain, immediately under the place where the cranium had received a laceration, or even in which the tumor had not been applied, or any portion of the cranium exposed."

Persons of the brain, in the greater number of instances, in which it has an opportunity of observing it, was accompanied either with tumor or fungus, and with symptoms of congested brain. In a large case of the tumor of the cranium, produced by a swelling left, and followed by a fungus of the brain, the fungus took place in the lower extremities. In a case of tumor, given by a surgeon to the right side of the forehead, and in which several of these had been found in most the brain, a large fungus protruded. The fungus of the forehead was followed by the fungus, which, situated under the skull, protruded, and the portion of the brain. In the present of the case, excision was made to the fungus, portions of it were sent off by the patient, and all of it that was exposed to the cranium was being poured off by the knife, with an incessant absorption, rather than suppuration, of the symptoms. In the death of this patient, nearly the whole of the right hemisphere of the brain was found converted into a soft pulpy mass. The left

hemisphere was not changed in structure, though with vascular impregnation appeared on its surface.—(*See Dr. J. Thomson's Report of Observations made in the Military Hospital in Belgium, p. 75, 28.*)

From the observations of Mr. Stanley, we are placed beyond all doubt, that a part of the brain is actually associated with the substance of the tumor, and he thus confirms the opinion formerly maintained upon this point by Quain and Ligon. This, in the first case with Mr. Stanley has occurred, "the whole of the brain was sliced off with a scalpel. During the operation, the boy gave no manifestation of feeling pain, although not unconscious of what was being done. Considerable hemorrhage took place from the surface of the brain, exposed by the removal of the tumor, the blood being thrown with great force, and to a considerable distance, those numerous vessels, which were attempted to be secured, but ineffectually by ligatures. After a short time, however, the bleeding ceased. On examination of the part, which had been cut off, the exterior was found to consist usually of a layer of the organized blood; the rest of the substance of the brain, presenting a natural appearance, the distinction between the cerebral and medullary matter being easily seen, with the convolutions and pia mater lying down between them." In the description of the death, "all that part of the dura mater subject to an abnormal aperture, through which the tumor had protruded, was black, bloody, and much thickened. The exposed surface of the brain, from which the tumor had been cut off, exhibited a somewhat red brownish surface; a state of degeneration, which extended deep into its substance. About an inch of red and dark-colored fluid was found between the dura mater and the exposed surface. Several small effusions of blood were met with, both before the operation and in the substance of the brain. The arachnoid membrane was thickened and congested with hemorrhage. The vessels on the surface, and in the substance of the brain, were remarkably full of blood. The lateral ventricle was large, and filled with transparent fluid, and there was some fluid between the membranes in the base, and, deep half, the quantity from these two sources was very little soluble."—(*See Med. Obs. Trans. vol. 3, p. 15-17.*) In another description, a considerable quantity of purulent fluid was in the arachnoid membrane, in each lobe of the brain.—(*See Med. Obs. Trans. vol. 3, p. 15-17.*) In most of the cases of tumor of the brain, which I have seen, the patient was in the acute period of the disease, but, however, under the influence of the operation. The tumor, paralytic, and some symptoms of congested brain, noticed by Dr. J. Thomson, did not take place till the latter stage of the disease, and then consisting of the paralysis and weakness occasionally observed.—(*See Med. Obs. Trans. p. 28.*) The disease is usually attended with great frequency of the pulse.

With regard to the cause of the protrusion, it is a subject very difficult of explanation, because if the origin of the tumor depended simply on the removal of a portion of the skull, or on any changes of the dimensions of the brain in expansion, the tumor would always follow such causes, and proceed in all patients. From the particulars of the description, performed by Mr. Abernethy and Mr. Stanley, and those related by Dr. J. Thomson, it is given, that the tumor would be a disease associated with depressed changes throughout a great part of the brain.—(*See the Large, Med. Obs. Trans. vol. 3, p. 15-17.*) The symptoms of the tumor in fatal cases are not pain and degeneration: after death large effusions of serum, and signs sometimes of blood, and paralytic action, are observed. These appearances have led some to the disease being associated with inflammatory action within the brain. It is highly probable, however, that a tumor would be only produced when there depressed changes are combined with the removal of bone. The changes alluded to may be supposed to exist in the increase in the great vessels of the skull, and thus a disposition to protrusion, as rapid as the tumor and other fluids are effused. This statement, however, can only be received as an hypothesis, for we do not find, that in case of the disease, described by Mr. Stanley, there existed a considerable space between the upper surface of the right hemisphere, all around the margin of the parietal and the lateral surface of the right outer table, in every other part, the internal table

and inflammation, this affection may be removed by applying the later planter soap, containing a large quantity of Winc. Some persons are often annoyed with this disease. According to reports, this is most frequently owing to a morbid state of the person (i.e. that one with a person who has an arid imitation, and a cold in the mouth, spiritus—*Chapman's Medical and Surgical History*, v. 2. See also *Practical Operative Surgery of the Eye*, p. 207, &c.)

INFLAMMATION OF THE GASTRIC MUCOSA.—*Inflammation of the Gastric Mucosa.* A further and partial species of gastric pain, or rather a combination of this affection with gastric ulceration. It is particularly characterized by the continuous or interrupted nature of its disposition to attack stomach, or ulcers, in crowded hospitals, or other situations, where, owing to these causes are brought together, and to the agency to remove the web partly affected by a gastric pain, or gastric ulceration, is taken on from its original nature. It is described—(*Practical, Foreign, French, and Med. Chir. v. 121*). It is generally believed to be characterized from its course or trend to another, by its local pain nature; but, whether the nature can be transferred only by actual contact, or by the way and through the medium of the atmosphere, is a question on which the most widely differ. The first origin of the disease, however, is a mysterious subject, which cannot possibly be explained so far as to admit of any principle, as will be hereafter noticed.

Thus, the description of Mr. Blackadder, it appears probable that several of the ancient writers, in their descriptions of that mysterious bleeding ulcer, must have alluded to the character of disease which is more nearly characteristic of gastric pain. Besides this use of the term gastric, which, according to the modern French writers, is the most correct of describing this morbid, several of the modern writers also have employed the term gastric ulceration, as, for instance, *Alton, Pallas, Kollmann, Avicenna, Galien, &c.* The only doubt whether these authors actually referred to local gastric ulceration upon which was being formerly described by the modern writers. But on this point, I recommend Mr. Blackadder's valuable treatise to be consulted.—(*P. 121*).

Although La Motte published a system of hospital hygiene in 1722, under the name of *hygiène*, and stated that it was derived on the 18th of June of Paris, the first distinct account of this disease is contained in the 3d vol. of the *Transactions* of the Académie, published in 1763. In the year 1766, Dumas, who was elected President of the Académie of the Hôtel-Dieu at Lyons, also published a short treatise on the disease. The first very accurate description of hospital hygiene in the English language appeared, in the 9th vol. of the *Lancet Medical Journal*, printed in 1766. The account is entitled, "Observations on the Fever of the Hospital, by Mr. Gibber, surgeon of the Royal Navy." In the notice of Dr. Keil's works on *De febre*, published 1767, there is a section on this subject, entitled, "A clear account of a morbid fever, arising on some, and of the method of destroying it." In 1780 Mr. Gilbert Blane, in the third edition of his book on the Diseases of Soldiers, gave an account of hospital hygiene under the name of *typhus* (short), and Dr. Ferrius, in the 3d volume of his *Medicina Militaris*, published in the same year, described that affection by the same appellation. In the third volume of the same work, Dr. Ferrius added to his first account several valuable communications, relating to the disease, received from surgeons of the royal army. Mr. John Bell also made hospital hygiene the subject of particular notice in the first volume of his *Principles of Surgery*, published in 1801. According to Dr. Thomson, new excellent names were first published in at the university of Edinburgh, the first entitled, "De Gastritis Continua," by Dr. Leslie, in 1811; the second by Dr. Charles Johnson, in 1815, under the title of "De Gastritis Continua Nuncupata."—(*See Lectures on Inflammation*, p. 456—458).

Previous Thomson's account of the subject, published in 1811, translated the 18th January of the disease at that time noticed. After afterwards gave a very fair account of the *typhus*—(*See French Med. Chir. v. 1, p. 226, 228, 229, 230, 231, 232*).

These descriptions were followed by the valuable notice of *Hospital*, entitled, "Mémoire sur la Contagion

des Foyes et des Ulcères vésicaux, par le nommé de l'Amateur d'Hôpital," 1810; some interesting observations by Dr. Huxham, in the *London Medical Repository* for March, 1810; a paper by Professor Broussais, of Leyden, in the "Annalen der Medicin Med." vol. III, 1812; and the treatise of Mr. Blackadder, which contains some of the best accounts of the disease occurring in an affection, and is entitled "Illustrations of Phlogistic Gastritis," from London, 1816. To these publications one is to be added the interesting remarks of Mr. R. W. Black on *Shocking Typhoid*, contained in the seventh volume of the *Med. Chir. Trans.*; and those of Dr. Budge, inserted in the third volume of the *Ann. Med. Chir. Trans.*

According to Mr. Blackadder, who is a literary in the domain of the complaint long ago expressible by the direct application of the infectious matter, when the morbid matter which produces the disease, has been applied to some part of the surface of the body, from which the morbid has been removed, as by a blister, cut, or such small vesicles that appear, which are filled with a watery fluid, or bloody serum, or a red or reddish-brown colour. The situation of the vesicle is generally in the edge of the pore. Its size is not unfrequently that of a split garden pea, and is easily detached, the pellicle which covers it being very thin. When the vesicle is filled with a watery fluid, and has not been ruptured, it exhibits the appearance of a greyish mass, or red-coloured dough; but when it contains a dark coloured fluid, or has been ruptured, it presents the appearance of a thin, confluent of blood, or a dirty brownish black mass. During the formation of the vesicle, there is generally a change in the sensation of the skin, some patients within periods feel like that of burning of a fire.

After a vesicle is formed, it spreads with pain, or less rapidly, until it occupies the whole surface of the original sore, and soon left to itself (which seldom happens), there is little or no itching, but the slight itching daily greater thickness.

When the formation of the disease has been interrupted, the stage sometimes becomes more frequent and more phlogistic, sometimes gradually subsides; and such is frequently the rapidity of the progress, that even in the course of a few hours, a very extensive inflammation will be formed, while the parts in the vicinity remain their usual healthy appearance. The morbid, the edges of which are well defined, is filled with a thick, glutinous matter, which adheres strongly to the adjacent parts. When this matter is removed, the surface appears presents itself of a fine granular texture, which is almost all features, impregnated of extreme sensibility, and is very apt to bleed when the repetition of bleeding is not performed with great caution. At each decision the character of the disease is found changed, and if there are more than one, they generally run in each other. The progress of the disease is much quicker in some individuals than others, but it never ceases until the whole surface of the original sore is occupied. The stage sometimes previously becomes of a dusky or burning kind; and after about the fourth or fifth day from the time when the morbid matter has entered by the skin, or otherwise, at the period of what may be termed second, or inflammation, the symptomatic vesicles and glands are apt to become affected. The discharge becomes purgative, its colour varying from a dirty yellowish white, to a mixture of yellow, black, and brown, depending upon the quantity of blood mixed with it.

The most parts in the immediate vicinity of the sore, daily become more painful, tender, and inflammatory; and a great number of cases, particularly in those of phlogistic and irritable habits, an attack of acute inflammation spreading superadded, and is accompanied by a great increase of pain, the sensation being described to be such as if the sore were burning. The period at which this inflammation begins to subside is by no means regular. Sometimes it subsides in the course of two days, and sometimes it continues upwards of five, depending very much on the constitution and previous habits of the patient, as well as the treatment that has been adopted. During the progress, the skin, which looking red frequently swells along which is formed on the skin, becomes more and more thick, and of a greyish consistency. Hence the form of disease is partially covered by green, yellow, greenish. In the course of a few days a very extensive

able in their descriptions of the state of the tongue. Dr. Wilson found it brownish or blackish; Depaul, whitish or yellowish (*Praxis Med.* t. i, p. 125); and Mr. Blackadder, covered with a white spot.—(*P.* 22.)

It is related by Mr. Blackadder, that when the disease attacks a large vessel, the whole surface of the tongue is immediately affected from the first; while in other instances, the disorder manifests in a spot, the size of a pea. When the patient is of an inflammatory diathesis, the sore is generally attended with acute inflammation between the second and fourth days; and the tongue is swollen and of a gummy consistence; matter of a strong and profuse colour, and of a dirty yellowish gray colour, begins to issue out at its edges, and becomes daily more copious. The inflammation gradually subsides, the slough becomes brown and finally detached, leaving the subjacent vessels, nerves, &c. exposed, and the slough is completely exposed. When the constitution is not prone to acute inflammation, the slough assumes long placement; the discharge is very copious, and increases as the slough, which flows northward, diminishes, until the detachment of a single, hard projection, rising up with notwithstanding a slight recurrence of the phlegmatic discharge, the parts laid up by the almost incessant operations of nature. However, most commonly after the matter is exposed, they continue to be gradually absorbed, their connecting cellular matter is completely destroyed, and they are left covered with an extensive fleshy-looking surface.

According to Mr. Blackadder, when a necrosis has been created, it yields sometimes to a great cure, and quickly restores the occurrence of a large quantity, being altogether deprived of vitality. When a tumor, however, is created, but has become inflamed, it generally acquires a pale colour, with an appearance as if it were covered with a fluid, and occasionally before being mortified, acquires a very surprising look—but when an inflammation supervenes, the proper location of a pure bright color, wears away daily, and the patient loses all power in them. As the disease advances, the integuments are undermined, and finally, and sometimes from small vessels, a common occurrence, but in a more advanced stage, some of the large vessels are apt to give way, and the bleeding from them frequently destroys the patient.

When a stasis is the case of the disease, and the patient is of a phlegmatic habit, or considered as free from the symptoms now begin to indicate the existence of an intense inflammation, arising through its whole substance, the transference, pain, and heat incommensurably, so that in a few days, the slough shall have enlarged more than twice its former size, being at the same time again increased, and causing the most excruciating pain. In this state, the patient has, in some instances, become delirious, and has been cut off by an effusion taking place into some of the larger vessels. It more commonly happens, however, that gangrene supervenes upon the inflammation and cellular membrane large sloughs are thrown off, and some of the large blood vessels giving way, the patient sinks under the effects of repeated hemorrhage. For it is commonly found, that the usual means of stopping hemorrhage from a stasis, are, in such cases, either ineffectual or totally inefficient.

Sometimes the progress of the disease is a stasis, in more gradual, but in the end nearly as mild; the inflammation is now in low state; there is comparatively but little transference, and the pain is much less violent, but the discharge is much more profuse, and the cellular membrane subsiding, the transference and matter is rapidly dissolved. Hemorrhages generally follow on later than in the preceding instance, but it is the most conspicuous of them.—*Blackadder on Phlegmonia Gangrenosa*, p. 22-23.

It is observed by Wilson, that every vessel in the system which receives blood powerfully the degenerative action of hospital gangrene. (*Thomson's Lectures*, p. 139.) A fluid issue at variance with the occurrence of hospital gangrene (*Praxis Med.* t. i, p. 125); but intended to refer, as I conceive, to those in which the disease, instead of other degeneration is seen for several days successively, limited in the order of the progress of the disease, yet not until day. I have seen the same thing frequently observed in rheumatic phlegmonia, as well in the groin as in the arm.

As for the smaller arteries, they are quickly destroyed, together with other parts.

In some rare cases says Dr. Hennen, I have seen the femoral and axillary arteries pulsating violently, and apparently unaffected with disease; while all the surrounding parts were completely destroyed. But in a vast majority of cases the blood vessels partook of the general disease, in which they were involved. They were not only completely separated from their natural covering, but their coats slough away at the immediate point of disease, while the portions remained beyond the apparently affected spot. Hence, our ligatures for aneurism failed on the main trunk, and all my attempt on the artery was invariably fruitless. We were here entirely induced by the use of artery canulas placed above the seat of the disease, and thus were done harm on the femoral, and trace on the axillary artery know the (catheter) the former built on the card, and of the latter on the second day after ward. Dr. Richardson further remarks, that in general the great vessels detached long after the first state of exposure of the disease had ceased, and that, in every case, the critical day of the disease was always decided.—(*The Military Surgery*, p. 227, et 23.) The absorption of the large vessels is slow, when taken upon the femoral artery, appears sufficient to these cases, and the tendency to rapid absorption in the arteries is the staining of the ligatures; the formation of an effusion compression is the softening of the vessel, the whitish green in them, color of mortification, and the general incapacity of nature in examples of hospital gangrene to establish any process which can be considered as ultimately aversive inflammation.

In the last stage of the disease, as it occurred in the military hospitals at Belton, the gangrened tissue was completely covered with bloody mucus, and in lifting up the edge of the flabby slough, the probe was fixed with dark colored granular blood, with which all its track became intimately filled. Repeated and copious venous bleedings were ordered, which rapidly cut out off the patient. The sloughs, whether they did get spontaneously, or were detached by art, were quickly removed by them, and brought into view thickly matted spots of arterial blood. At length, an artery gave way, which was generally too dangerous in the attempt to secure it with a ligature. The hemorrhage, on other pressure, was soon applied, but it was, for while it checked the bleeding, it accelerated the death of the limb, which became profusely mortified and too likely to fall. Inward medicines were used, and with success, in every case, and frequently, down to the "house Officer," however, the patient survived the acute state of the disease, and sank under severe irritation, as symptoms of putrid matter, and extensive loss of action, with common hectic symptoms.—*See Thomson's Mil. Surgery*, p. 237, et 238. In the disease at Belton, the skin and cellular substance around the parts originally and passively affected. This, says Dr. Hennen, was common, even in the living body; but in discussing the disease of these parts was frequently observed to spread much further than external appearances indicated, as a diseased track was often found running up into the groin, or thigh, and completely directing the muscles and great vessels.—(*The Military Surgery*, p. 238, et 239.) When the disease had reached the inside of the chest, the state of the lungs varied in two cases, and the pleurae was a third, colored with purgous matter, and when discolored by the disease had been attacked, the often played the same appearance on the liver.—(*P.* 239.)

Hospital gangrene must be regarded as one of the most terrible and dangerous complications in which wounds and ulcers are liable. When the action of vitality is large, or of long standing, the disorder becomes great, carries, leaves its marks indelibly, and the relapses prove exceedingly obstinate. The same thing is said to happen when it affects persons suffering under aneurism, or venereal complications. Hospital gangrene prevails particularly in the groin, and axilla, when it communicates deep extended wounds, attended with badly fractured bones. All the soft parts of the injured limb are then frequently observed to be progressively destroyed, and the inflammation, follows a vicarous order in typical synapses, frequent hemorrhages, or hectic complaints. From what has been stated, however, the disease varies

neighbourhood, and inevitably destroying the ablest and patients to a large extent."—(*Principles of Military Surgery*, p. 218, of 2.)

The effects of hospital gangrene should be carefully distinguished from those of the disease. There attacked with hospital gangrene are not affected in any degree, like scurvy, when, by the use of vegetable diet and lemon juice; and they occur among men who are not upon fresh meat and vegetables, as scurvy is. They do among those who have been full altogether upon salt provisions.—(*Thomson's Lectures on the Venereal*, p. 482.) Hospital gangrene is always always accompanied with severe febrile symptoms. (See Dr. Ferrius (see Dr. Lind), it may indeed be doubted whether there be any such as are purely and truly syphilitic. The disease is altogether of a chronic nature; and surgery may be fairly resorted to along its advanced symptoms."—(*Treatise on the Syphilis*, p. 200.) In cases of hospital gangrene, the general symptoms of scurvy are also absent, such as swelling and bleeding of the gums, livid tinge to the skin, and the fleshy part of the legs, indolent swellings, &c.

Hospital gangrene (says Boyer) is a species of brand gangrene, when attacks in some degree *spontaneously* the wounds and ulcers of patients who happen to be crowded together in an unhealthy place.

Its essential causes are: the situation of its hospital upon a low marshy ground; the vicinity of swamps, or of the lowlands, the unwholesomeness of the food, such as the stings for their use; the crowded state of the wards, especially when they are small and badly ventilated; lastly, every thing that tends to corrupt the air which the patients breathe. An infected atmosphere may produce in the most simple wounds infatigable changes, partly, as Boyer conceived, by its insensible action on the surface of the wound, but, no doubt, principally, by its partial diffusion upon the whole exposed surface. The long-continued action also sometimes produced striking and extensive progress of an epidemic kind, or, at least, a state of the constitution, under the influence of which all wounds and ulcers eventually take on a bad aspect, and were often accompanied with a most gangrenous character. Appearances such as phagedenic ulcers, or the bloody pus, in the two hospitals of Herculaneum, and he states that the most powerful antiseptic was of little avail against the disorder, which often involved the slightest scratches.

In general, this epidemic species of gangrene is not observed in our best hospitals, but in those which are crowded out of the central parts of cities upon high ground. Hospital gangrene is only seen in any season; but it is most common after the rainy season of winter.

A false constitution, sexual excess, venereal disease, or small festering, venereal disease, gonorrhoea, and, types of a diaphanous type, are also recognised by the French surgeons as its predisposing causes of hospital gangrene.

The investigations of Ferrius, and those of some other physicians, certainly prove that hospital gangrene may be ascribed to the most minute miasmata or even to a subject of the best constitution, and lastly, the great air, by merely making it contact with such wound or ulcer, persons, but, as scurvy, impregnated with the infection of this peculiar disorder. But this insinuation is supposed to be the more alarming, and to have effect the more quickly, its consequences as principal have been more exposed to the influence of miasmata as are themselves capable of producing the disease, and also its propagation to the kind of resolution predisposed to it.

Although the essential nature of hospital gangrene has been generally admitted by all the best informed surgeons on the subject, the description not conceived by Dr. Ferrius as having a good foundation. Modern authors, however, have not joined this latter opinion, and Dr. J. Thomson, Dr. Ferguson, Mr. H. Blackader, and Mr. R. Wilkes, all believe that the disorder is infectious. "The contagious nature of hospital gangrene," says Ferrius (Thomson agrees as to it) is sufficiently proved, for, by the fact, that it may be communicated by simple changes, bandages, and similar, as persons at a distance from those infected with it. Still, by its having been observed in which the slightest of successive cases, when once exposed is deemed infected persons; and that even in situations where the medical men so employed

did not live in the same apartment with the infected, still, by its being able to trace its progress the faculty from a single individual through a succession of persons. Still, by its attacking recent wounds, as well as old ones, and that in a short time after they are brought near to a patient affected with the disease. Still, by its being able to produce the progress of the disease in particular situations, by removing the infected person, before the contagion, which has been cast, but that time to operate. Still, by its continuing long in some particular ward of a hospital, or in one particular shop, without appearing in other wards, or shops, it seems to be in some instances between the infected and uninfected."—(*Lectures on the Venereal*, p. 494.) But although there can be no doubt of the disease spreading partly by its contagious nature, it appears to me equally certain that the majority of cases is also often increased by the continued operation of the agencies which produce the earliest instance of the disorder in any particular hospital. A slender belief is expressed by Mr. Boyer—(*See British Med. Chir. Trans.*, vol. 3, p. 223.)

It is alleged, that when once a patient has taken the infection, he cannot avoid the consequences, whether precautions be or may adopt. Thus, Boyer informs us, that he has seen hospital gangrene take place in wounded patients, who, in the hope of escaping this epidemic infection, had quitted the infected hospital, and retired to private situations, where they breathed all most wholesome air.—(*See Trans. of Med. Chir. Soc.*, p. 323.)

The bad state of the air of a crowded hospital, as Mr. Blackader observes, is a ready means of accounting for the origin of phagedenic gangrene, but there are various reasons for supposing such explanation not altogether satisfactory, and he mentions a case, in which the wound of a soldier was found infected with the disease on his first arrival at a hospital, after having been accidentally detained, with one other wounded comrade, for five or six days, partly in an open building, and partly in a tent, where exposed to the open air.—(*See* Dr. Thomson's *Lectures* give an account of about thirty fresh wounded men, in whose hospital gangrene had appeared in their journey from Vienna to the hospital near Buda.—(*Principles of Military Surgery*, p. 218, of 2.) Dr. H. also remarks, that some men in quarters were affected with this disease. And according to Mr. J. Bell, "there is no hospital, however small, dry, or well regulated, where this epidemic does not beget and take."—(*Principles of Surgery*, vol. 3, p. 122.) These variations of the opinion, that the disease itself attacks the patient *exclusively* and *spontaneously*, have led to the conclusion of the character of Mr. Blackader.—(*P. 123, of 2.*) Beyond remarking, that the progress of the disease almost appears to have depended upon the state of the atmosphere in 20, 40, in almost every instance, he found the propagation of the disease to be almost exclusively of the miasmatic nature to the center. However, he gives Ferrius in the belief, that it may be transmitted through the medium of the atmosphere, an opinion which Mr. Blackader admits, as rather considers as very rare, and only possible where the efforts are allowed to be accessible in a most violent manner, as to be possible a violent fever, which made it would also regard as impossible in itself.

(*The Principles of Surgery*, p. 125.) On the whole, I am disposed rather to view the view which Mr. Blackader has taken of the manner in which this disease is communicated the most correct, and that, while particular cases of the air and constitution certainly modify the disorder, they cannot generally have any share in giving origin to the disease.—They generally, however, as given, have either to be taken, that hospital gangrene sometimes takes place having been conveyed from any person previously affected, it is impossible to admit, that the epidemic example of a soldier took gangrene, cannot take from the operation of some instrument, capable able circumstances in the atmosphere, or, in other words, from the state of the system itself. Nor can a doubt be conceived, that at all events, the disorder is not only to be taken as provided, badly regulated hospitals, and in those appear more extensively and markedly than in others, which are well regulated, properly ventilated, and healthy situated. But the most objectionable by Ferrius, that hospital gangrene may originate from the

the enlarged cellular mass, and become visible. The cyst, which, in some instances, is scarcely perceptible to the unaided eye, we found to have become visible first with dark, and some of them not large enough to reveal the end of a finger. Which the tumor is largest at this condition, the pain is remarkable to become more definite towards the bottom, and as this symptom disappears, only one large cyst, filled with fluid, is left behind. Hence, according to Scarpa, a fluctuation is usually distinguishable in the lower part of the swelling. The fluid contained in the cyst is generally limpid, but sometimes yellow, albuminous, crystalline. The size of the swelling, however, large or small, corresponds to the point at which the spermatic vessels pass the testis, or, at most, it extends a very large behind the sperm, and between the two there is a considerable growth, which varies in length and extent. Scarpa further informs us, that if the tumor rapidly increases, a depression is felt at the testis, and a hard part, striking off all communication between this and the rest of the tumor. (Johnson and Hewitt and Gordon's Synonyms, 4th. Edition, 1833.)

That the cellular membrane of the cord is often distended with air, Scarpa states, when the sperm is not passing, and the pedicle of the tumor situated lower, and hence it is a symptom attendant on the cure, which has been described in the hydrocele, not only by him, but by many other writers, in which such cases were mentioned as the result of the cure of the cord, but not in supposing that it is a very uncommon case. The following is said by Mr. Pott to be the state of the disease, when it assumes this form. The internal bag is free from all appearance of disease, except that when the skin is not completely incised, the sperm falls, and larger rather more on that side than on the other, and if supposed to pass on the path of the sperm, the latter, the testis, with its epididymis, it is left perfectly unharmed, but the sperm, whether retained, or in any manner altered from its natural state, the spermatic process is considerably larger than it ought to be, and looks like a vein, or like an intestinal hernia, according to the different size of the tumor. It has a protuberant head of firm, though not the bottom than at the top; by gentle and continued pressure it seems gradually to move or go up, but drops down upon immediately upon removing the pressure; and when as firm as a tumor, as it is not so, it is attended with a very small degree of pain or tenderness; which sometimes is not felt in the scrotum, where the tumor is, but in the testis.

According to Scarpa, the shape is at first nearly cylindrical, and does not become cylindrical till afterwards. Scarpa says the swelling may be, the pain never appears as soon retained under the weight of the penis as in a common hydrocele of equal size. When the lower part is approached, the fluid remains towards the groin slowly and difficultly, when, in the hydrocele of the spermatic cord, the same kind of pressure at once forces the fluid to the apex of the tumor, and defends it, and the bottom cannot be felt as in the inflated hydrocele below the swelling.

When a diffused hydrocele of the cord extends into the testis, it is not easily distinguished from a common hydrocele. In both cases, says Scarpa, the tumor is at first of a cylindrical shape, and afterwards becomes pyramidal; both kinds of structure are soft and flexible, both little if at all movable, and both subject of contraction with difficulty. No pain, the first sensation at the testis, if it is indolent, will be derived from the circumference of its upper part not responding, while the patient continues to be there, though Scarpa has not a few exceptions.

With this, it is hardly an object of cure, and only kept from being less obvious by its position (a supposition), but when it is large, it is very inconvenient, both from size and weight, and, according to Pott, the only method of cure which is advised, is the first incision of the scrotum over the swelling, is the first incision of the cord. This is especially true, when the disease is accompanied with constitutional disorder. Thus Pott and Scarpa have known them, however, attended in its extreme, decline here in first incision. As the extension of the cellular tissue, in which the hydrocele keeps, all disseminate together, it appears to me, that the necessity of a free incision for the discharge of the fluid is not so

against, as the observation of Pott, which leads us to suppose; and thus a moderate opening would be likely to answer every purpose, with much greater safety.

THE ENLARGED HYDROCELE OF THE SPERMATIC CORD.

It is by no means sufficiently, especially in children. The same kind of disease observations occur in the most frequent of the sperm, and sometimes it is thought to be common (see Johnson and Hewitt and Gordon's Synonyms, 4th. Edition, 1833). Scarpa is of opinion of the nature, and has been extremely described by Albinus, Celsus, Pott, Scarpa, &c. When Mr. Pott says that the disease is not contagious, it ought to be generated, that its frequency, amongst the greatest than that of the diffused hydrocele of the cord, considered as a distinct disease independent of general leucemia, is not still equal to that of the hydrocele of the testis or epididymis. Retained hydrocele, therefore, the proportion of encysted hydrocele of the cord to that of the latter description, is not more than as one to two hundred. (Nassey, Clin. vol. 4, p. 202, &c.) According to Mr. Pott, the swelling is usually situated in the middle part of the cord, between the testis and groin, and is generally of an oblong form. Whether it be large or small, it is possibly very heavy, and consequently the distention of the scrotum within it is not always insensibly or easily perceptible. It varies in pain, but is not to be very large, unless it is under very necessary action. It is generally contracted, and the spermatic cord, some with the cord of the testis above, is that of the right cord of the spermatic being so. The testis and its epididymis are perfectly and distinctly to be felt below the tumor, and are absolutely independent of it. The upper part of the spermatic process is the greater is most frequently very distinguishable. The spermatic does not much rise in comparison with the fingers, and when slightly struck upon, sounds as if it contained fluid, &c. It sometimes is elevated from pressure of the spermatic process, it is not affected by its swelling, &c.; and it has no effect on the drainage of urine.

Scarpa observes, that the diagnosis is more difficult when the encysted hydrocele is considerable, because the testis is hidden, as it were, in the tumor. Scarpa says, if the portion of the swelling which projects beyond the scrotum is not so large as the testis, it is not so, and very small, when the testis presents the character of a collection of fluid, the first and smaller portion in the testis is its healthy state, and the latter portion is encysted hydrocele in the testis. This kind of hydrocele only be known from either of the testis by its condition, smoothness, and free from pain.

The two diseases, however, with which this kind of hydrocele is most likely to be confused are a hydrocele of the tunica vaginalis, and a hernia. The difference is which it differs from the first, but not from the second.

According to Pott, the first state of the upper part of the spermatic cord, while the tumor is in its first stage, the gradual accumulation of the fluid, and consequently the gradual growth of the swelling; the labor and constant state of it, its being impossible of reduction, or return into the body from the first; all being usually attended by the patient's suffering or discomfort; and the interrupted freedom of the first drainage per anum, with always distinguishable from an intestinal hernia. It is not to be mistaken for a retained sperm, and in its characteristic features, it is not so much attended.

Mr. Pott met with an encysted hydrocele, situated so high towards the groin, as to render perception of the spermatic vessels very obscure, or very impossible; but then, the size and appearance of the tumor, and the absence of every symptom proceeding from interruption of the intestinal canal, were sufficient proofs of the true nature of the complaint.

The cure is described by Scarpa as consisting of first incising the middle of the tumor, and making in the cellular structure of the cord, a small hole, and then, with a needle, the tumor is incised, and is then placed within.

In general, the pressure of an encysted hydrocele pushes the testis a little lower in the scrotum, and either upwards, or rather downwards. Scarpa does not think, however, as we have seen, considerably raised, and directed to the tunica vaginalis.

made of silver, was just small enough to pass with ease through the entrance of the oocyte, and five times long. The third instrument was a probe six inches and a half long, having at one end a fine steel hook-point and at the other an eye, which raised the pedicle. The uterus consisted of so much white serous silk, as would just pass easily through the vagina, and yet felt it. The thickness of the uterus, however, was not so great as the latter part of his practice. Having passed the infundibulum and anterior part of the uterus with the force, withdrawn the pediment, and distinguished the vesicle. Sir Paul used to pass the second cannula through that of the incision, for the upper part of the uterus vaginalis, so as to be felt better. The probe, armed with the hook, was next introduced through the latter opening, and the point pushed through the upper part of the uterus vaginalis and uterine. The silk was then drawn through the cannula, until a sufficient quantity was brought out of the upper orifice. The two infundibula being withdrawn, the operation was finished.

Discussion

Dr. Moore introduces the first use of injections for the specific cure of hydrocephalus in a very summary of his case, and was employed with spirit of wit. The reduced a cure; but the disadvantage was so evident, that he afterwards tried a rather injection, which was that of truss. However, incident in his *Memoriae Celsæ*, published at Marcellus early in the seventeenth century, advised injecting a solution of substance in the water, and he has related cases of success. Mr. S. also noted that of spirit of wine, which cured the hydrocephalus, but not without causing dangerous symptoms, and two subsequent attacks in the scrofula—(effusion of Serpigny) Douglas, Le Duc, and Port all disapprove of injections in their works; though for James Earle (1808) it is, that the latter lived to allow his opinion on the subject.

The violence of the inflammatory symptoms, consequent to this first employment of leeches, for the radical cure of hydrocephalus, arose from the inflammation being too lightning. Sir James Hall, in a last, reported case for several years. He found that it had been tried with success in France; its strength is *excess* as great as to render it trifling; and it may be readily weakened. However, as the strength and other qualities of each wine vary considerably, Sir A. Cooper prefers using a solution of the substance of zinc, 7j to a pint of water. (*Lancet*, vol. 2, p. 87.)

"I have constantly used says Mr James Earle; about two thirds of nine to ten yards of water, if the parts happened outside, and we put at all new prepared by the first process thrown in, I have with my own eyes, and added to the preparation of many of the country, if the operation was perfect, and it appears suitable, I have increased the proportion of water, so that I have lately been generally guided by the degree of sensation which the patient has expressed. I have lately used pure water mixed with wine, and found it answer as well as other antispasmodic remedies."—(Treatise on the Hydrophobia, p. 161, ed. 2.) In the preface, the author says, that he too long assumed the pain with a stupor, which he once engaged on account of the being well able to spare a third, during the operation, to turn it, and the consequently being found ineffectual. A pipe, one end of which is made to fit into the osseous orifice of a broken, the other adapted to receive the neck of an elastic bottle, with a valve or ball in its centre of the pipe, to permit the admission and prevent the exit of the vapour, will be found inferior to none discovered and applied.—(Earle.) When the patients are very large, six ounces may be made deeply lying into the hand, and waiting until the patient awakes, a more moderate dose before attempting the second trial, is advised.

It appears that the French *Flair* is a interesting case, that differs only by a minor detail in this manner, even when one thinks of a woman as essentially being loved in the context of a society. To be sure a patient with an egoism, even though the attitude was *selfish*—(See *Don Quixote* 162, c. 3, p. 224). Similar cases are also illustrated in the *Parsons Club*. The following is the common basis of egoism; the hypothesis is to be changed, not a social as in *egoism* and *egoism* part, and where the whole of the *Flair* is assessed, the quality of the *egoism* remains to be seen.

diverted to its former destination with the shunt injection. This is to be followed in 2 months by the part shunt five months, again the reverse, after which it is to be clamped through the carotid. The patient nearly died some days in the past, and then the kidneys on the right being removed, which symptoms rather gradually as they eased, that the situation of the shunt is likely to have the desired effect of securing the satisfactory degree of reconstruction. First plan, which was thought to be a high part of protection by the late Sir James Esdaile, may be deemed almost a sure means of obtaining a permanent cure, and being at the same time mild, is most judicious in Pott's, Pott's, and Gout's.

The treatment after the operation is exactly like that of the common shelled totemic *ana* *Hirudo* *hyemalis*, consisting of the use of Potentillae, gold pins, leeches, calico paper, and, above all, of a long kind of wrapping up the extremity. However, a strict antiseptic treatment need not be adopted, unless the inflammation becomes too violent, because a higher degree of it is necessary for the cure. Sometimes, Mr. A. Cooper even recommends his patients, when the inflammation is not quite enough to take away life, to lie still and walk about. According to Boyer, the indicated before of the treatment with leeches is injurious to the premature discontinuance of spirituous applications, and the too quick substitution of exercises for them, as well as the play of not letting the leeches remain in the trunk so long as long contact. (See *Med. des Sciences*, Vol. 1, p. 213.)

One criticism is frequently to offer before taking our leave of this subject. It has sometimes happened during the operations, that the vessels has drifted out of the incision, upwards, and its more recent incision extended in the substance of the *vertebrae*, as indeed sometimes happens, if the person is propelling and the ligaments, with all the cellular topes of the part, with a surrounding fluid, which may cause abscesses, sloughs, and other violent symptoms, to great raising the cavity of the *fluida ligamenta*, or producing a radical cure of the *Adiposities*, which, however, I have known happen often. In this case, as I have already related.—*See First Line of Surgery*, vol. 2. When such an accident happens, it is better to close the operation till a sufficient quantity of fluid has collected again. Sometimes, when the incision is strict, a great deal of it has passed into the cellular membrane, and the operation is irritable, the vessel's apical ends in the patient's death. Many times can be recovered, and very well noticed by Mr. A. Cooper.—(*The Lancet*, vol. 2, p. 26).

Hydrochloric acid is being used by applying it to the acetone solution of analysis of minerals in a chemical analysis. (Nelson). But the application frequently causes a great deal of pain and irritation, and, in common people, does not often succeed, to say the least, of it. (Nelson). However, in strong persons and children, the disturbance of the stomach, the irritation, the irritation, and a temporary headache, mostly when the acid is combined by the reaction of the acid. (Nelson). (Nelson, and Nelson, p. 33).

Disinfect the bucket vigorously with air, cold water, or even the fluid discharged, has sometimes effected a radical cure.—(See Supplement to *Physician*, p. 103, Vol. 194.)

A case is mentioned by Sir A. Cooper, in which with very slight, so the suggestion of it being a mild, undulating fever. However, very severe inflammation followed, and an abscess in the neck resulted. When an opening was made, the milk came out in clots.

There is a particular case, that has been called the suspected epidemics, by which is implied a collection of signs in the various variables, with a consequent action between the cavity of this substance and that of the peritoneum. It is not need to run this down by a and wine ingested. After the protruded blood had been returned into the belly, and while the tension between that and the walls of the various expands rose slowly increased and moved by a steady action, though, after being out the water in the cavity, and, to throw in the location. The swelling, it is said, suspended, without causing the previous management one might *a priori* expect, viz. inflammation of the peritoneum.

This kind of hydrocarbons has not been described by

and now regarded as proving very little more, than that the patients, supposed to have caught the disease by contagion, felt violent shivers at violent affections of the isolated nervous system, or that occasionally taking place even after the death of a very small amount of virus. It is clear enough that some of the cases were, at most, only phenomena of sympathetic hydrophobia.

With regard to another opinion, that the bite of a man or other animal, when severely wounded, may bring on hydrophobia, it is now entirely discarded as erroneous. The cases in support of it, recorded by C. Pouchet, Maresquis, Malgou, Zenger, Le Gal, &c., when critically examined, only prove that the patients were affected with tetanus or erysipelas. Hydrophobia, not arising from any infection; for, neither the mode of attack, nor the progress of the symptoms, in any of the examples, points are related with sufficient exactness, lead to the inference, that the patients actually died of tetanus.—*See Gal. des Sciences Méd.*, t. 47, p. 493.

Wrong notions, of a very dangerous tendency, have been generally entertained in regard to the disease, as it appears in the human race. The writers of the *British Disp.* in Dr. Ross's *Encyclopædia*, appears to have had superior opportunities of observing the disease in dogs; from this source I have collected the following instructions.

The post-mortem inspection, which when attended the complaint in the human subject, has been applied to the disease in horses, and has discovered it to be caused by the same nature, hydrophobia. This is a palpable mistake; for in numerous cases there ever remains a total want of water: on the contrary, dogs are in general very greedy after it. Neither being sleep, when quiet, nor dread of water, but frequently mixed with great freedom, as is proved by some experiments, of which an account is given, in *Mansfield's Journal*,—(T. 6, p. 324). Such irrational disposition has often occasioned a very fatal error; for, it being the received opinion, that no dog is mad who can lap water, some persons have been led into a dangerous security. Another equally false and fatal idea has prevailed, that every mad dog must be wild and furious; but this is so far from being true, that in the greater number of instances there is very little of that wild, savage fury that is expected by the generality of persons. "Hence," says this author, "as it happens that the most hydrophobic, characterizing the affection in the dog, is a reluctance, so it is evident that the term madness is equally so. If this instance have I even observed a total alteration of the mind; in very few have the mental faculties been disturbed. The disposition to do mischief is rather an increased irritability than absence of sense." In most instances, when those that are furious know the master's voice, and are silent. The irrational which is most frequently observed in a mad dog is a certain propensity in his manner; water always deprives him of his usual habits. In a very great number of instances the pathological condition is a disposition to lick at straw, bits of paper, rag, threads, or the smallest objects which may happen to be in the place. This is said to be particularly common in small dogs. "Often again there is only sensibility to licking the pieces of straw or rag." In one instance the approach of the horses was directed to us observing a very uncommon attachment to one puppy towards a kitten, which he was constantly licking; and likewise the odd case of a healthy pig, that was with him. An attachment to the sensation of cold appears in many cases, it being very common to observe these (the dogs) licking the cold feet, and claws, the horse's legs, early in the disease, but not their own extremities, and lap their own tails." As early attempts to induce dogs and pigs to very commonly observed, but particularly in cats. As the disease advances the affected dogs take little notice when they are approached, and lastly, the present animal, but, except in a moment of irascibility, they seldom attack the human subject. The irritability that induces them to lick is very strong; but understood as weakness, it is more like drunkenness than fury. A sick dog lap up at them always against their anger in a violent degree, and throughout the disease there is generally a wonderful remission of control, and the animals are with great difficulty restrained.—*See our Disp.* in Dr. Ross's *Encyclopædia*. In dogs, as well as pigs, a peculiar change of the voice is regarded as one of the

most important signs of the disease.—*See Mansfield's Journal, de Physiol.*, t. 1, p. 2, 1831.

Dr. John Hunter calculated, that one of every dozen of wild dogs about New Orleans are poisonous when they bite. That these animals, and wolves also, have a particular dread of fluid, is proved by fact. Thus, a cold wolf, at Florida, when under several fangs (Mansfield's Journal, de Physiol. vol. 4). Insects too bite and sting with without ceremony, and successfully.—(Mansfield's Journal, de Physiol. vol. 1831). And animals will sometimes eat as well as drink. Thus, the wolf which bit a lady person at Mexico, in 1815, was found on the morning drinking a shepherd's dog. And Dr. Gibbans speaks of a dog which was found dead because it eat and drank water, but, on a second dissection, it was killed, though not having lost its mind, when left a victim to hydrophobia.—(On the Bite of a Rattled Animal, p. 13).

When a dog bites a person, it should not be immediately killed, but merely restrained, by means of dragging it in water, the possibility of infection whether it was rabid is prevented, and great alarm is thus laid up in the minds of the wounded persons who bite. If the animal be affected with rabies it will soon be a few days. At the veterinary school at Alfort, when a dog has been bit, it is usual to confine it up for eight days before it is released to its master; dogs are seldom being considered the period when a dog is usually bitten, is not after being bitten.

My friend Mr. de Alfort had a large New-land dog, his river, which did not become mad at any stage had clapped from the period when it was bitten by another dog. As I saw this case, and the animal appeared with the particulars, I consider it as establishing a useful medical opinion, placing the most confidence in the plan adopted at the veterinary school at Alfort.

For additional details, relating to the disease as it appears in the dog, I must refer to the *British Medical Review*. Though, I have, in the last, it might be supposed, that mad dogs are not particularly distinguished by an inability to lap water, and by the degree of fury. These animals, when actually affected with rabies, lose their quiet nature; they are not been suspected of leaving the domestic, and have been allowed to run about, been killed, and often kept shut.—*See Mansfield's Journal, de Physiol.*

The cause of this peculiar disposition in dogs are at present unknown, and little more than conjecture prevails upon the subject. It is not generally known whether rabies sometimes originates spontaneously in these animals, though I believe this opinion is not generally ground; as, whether the cause be in the human species, it is propagated only by contagion. Thus the disease is frequently imported in consequence of one dog biting another, every body will know; yet there are many instances in which the mode of propagation cannot be ascertained. Sometimes it is probable, that many dogs, the disease is often communicated by contagion. It is observed that in some situations dogs are seldom affected, but the disease is usually to such animals being in a state of quarantine. The rabid animal, however, Mr. Mansfield, visited his den from the reality, by having been seen having perhaps a quarrel with him, but not to join the pack.—*See Treatise on the Impression of Rabies, and other Animals, vol. 1, art. 1.* I have heard that very commonly supposed to be the starting cause of the disease in them; but without much doubt. A very hot climate, or one exposed to the extremes of heat and cold, or any bad and irregular feeding, some partial starving, and hunger, their want of water, access to the kitchen, presence, visit, or vicinity of the dogs, may set down by themselves as causes of the disease.—(Mansfield's Journal, de Physiol. vol. 1, p. 1831). That the dog, when bitten, is not immediately poisonous, and may not transmit it, is well known by fact.—(Mansfield's Journal, de Physiol. vol. 1, p. 1831). And another has also been seen to be contagious in rabies, because the entire case, and is supported because, the goods being bitten, these animals usually quench their thirst.—(See Ross). This system of thought is very common, but it is not the case, as it is manifest enough in any body who has observed it, that over the volume of the *British Medical Review*, in 1831.

tion of what happens in the human subject, the same inferences should be drawn, as from experiments on animals, when the latter is so marked with spontaneous phases of a steadily infectious character.—(See, for example, *Philos. Mag.*, 37, p. 67.)

Although many cases are to be met with in the records of individuals and groups, leading to the conclusion that we have applications of the value of a value attribute to the second dimension of the human subject, they give rise to a hypothesis, the validity of which is subject to general discussion, and value to a definition which may be defined as the application of the value of a value attribute to the second dimension of the human subject, or, in other words, the value of a value attribute to the second dimension of the human subject, or, in other words, the value of a value attribute to the second dimension of the human subject.

Enzymes are also required, the nature of which is to be proved, that the hydrolyzable virus that takes effect through a second enzyme mechanism—(phosphatase, cf. *Abstracts, Genetics, Portland, Oda, vol. la, page 4, 13*). *Mathison in Abstr. de la Soc. Royale de Médecine, Ser. D*. But even this does not happen in the human subject as is clearly well proved by the consideration, that formerly victims of mass suicide in their homes in such the vicinities gained by the ritual of ritual suicide, yet those of them instructed hydrolyzable, from their local religious centers—*Monquellies, Abstr. de la Soc. d'Ethnologie, 1953, p. 15*. The example of the ritual, which is undoubtedly known a child without the least of effect, while it was dying of malaria, as recorded by Dr. J. Vargass, has been already referred. However, if hydrolyzable were apparently to arise in any case instance from the application of the atoms of a rigid grain to the inside of the lip, no positive influence could be taken from the fact, unless the action were also combined of increasing that there were no slight difference about the grain, or within the mouth, previously in each combination.

For the hygienic treatment to take effect, therefore, it is generally, if not always necessary, that the infection must either be directly applied to an abraded, wounded, or abraded surface. In the case of a bite, the bite is the conventional weapon, which at once causes the infection of continuity, and deposits the infection in the part. Had the mere abrasion of the skin and the application of the infectious saliva to the abraded skin, well often suffice for the tissue production of the disease. As the mode of contamination, therefore, is a true inoculation, it follows, that the danger must depend very much upon the quantity of infectious matter conveyed into, or applied to the part, the efficient manner in which the saliva is injected to the flesh, the extent and condition of the wound, and particularly the circumstances of the mouth of the individual having passed through an orifice, by which the saliva might possibly be effectively prevented from entering the wound at all. Hence, bites on the hands and face are well known to be of the most dangerous description, especially those on the face, the hands being sometimes treated with gloves.

From what has been observed, however, it is not to be concluded that the disease always follows, even when the natural system offers the line is decidedly weak, and even if the action is generally applied to the individual's elevated plane. In the contrary, reports are fairly positive, that in the great number of individuals even he by the same test this, and to places in efficient individuals, however, is crossed, only a group of the number are afterward attacked with hydrophobia. When the disease in the fate of the individuals caused by exposure to the ultraviolet of short length, the thickness of the crusts on the lower part, the most weak and superficial nature of the line, and division of the part, is more often made in which the disease sometimes were found in several individuals, it can only be justified by some unknown protection or influences to the constitution of the several individuals. Therefore, reports are more reliable when the test is performed on weak and high, but more susceptible of some than others, and more exposed to the ultraviolet light.

There are more fishermen in the town than the landowners. — Poor men and their dogs were killed by the steam road dogs, and every one of the dogs died at the dinner, it killed all the fish men around, though they would not offer money to give them any such as the dog every day. There is also an instance of

twenty persons benefited by the same road dog, of whom only one had the disease.

Dr. Mayhew has defined hydrophobia to be an aversion and horror at liquids, evincing a painful consciousness of the pharynx, and consisting of an ischaemic state of the pharynx. The disease has been observed in the human species, and others, in a building and great dread of drinking any liquids, soon after drinking a potent morbidness of the pharynx, occasioned most commonly by the bite of a mad animal. Others have suggested the following definition as most complete: reluctance, dread of cold air, of any thing drinking, and particularly of water, often arising from the bite of a mad animal—*Fury's Med. Diet.* However, the latter definition is, perhaps, equally objectionable, because there is not necessarily a dread of drinking liquids—*See Dr. Foulie's Case*, p. 81. While some authors represent it as a nervous disorder, others, among whom is Huxhamer, consider it as one of an inflammatory nature. In many systems of surgery, hydrophobia is treated of with purulent wounds, of one species of which it is usually the effect.

With regard to the symptoms of hydrophobia, they are generally many, in making their appearance, a considerable, but a very variable, space of time usually elapsing between their commencement and the receipt of the bite. Out of a table of 181 cases, none of the patients became ill before the seventh day after the bite, and only three before the eighth. It is preceded by Bourquin, that one patient, now lost by a dog in the morning, and was attacked with hydrophobia three weeks in the afternoon. Edin in this account was communicated to the author a long time after the occurrence, and not by a medical man, it deserves little confidence. Another case, advanced by Mead, is deprived of all its importance by the same consideration. These examples, as well as another reported by Astruc, in which the patient is said to have had hydrophobia in less than three days, after being wounded on the temples, can now be regarded only as specimens of symptomatic hydrophobia. — *Dict. des Sciences Méd.* c. 42, p. 761. There appears to be no intermediate period at which the disease makes its attack after the bite; but it is calculated, that the symptoms most frequently commence between the fourth and seventh days, and that after this time the chances of escape increase. Of fifteen patients, whose names Truffaut has acquired with seven were attacked between the fourth and seventh days; five between the eighth and twelfth; two a little beyond the latter period; and one after fourteen weeks. In May, 1794, gentlemen persons were bit by a rabid wolf near Brive, at whom they were afterward attacked with hydrophobia six days on the fourth day after the bite; one on the eighth; one on the seventh; one on the twenty-eighth; one on the thirtieth; one on the thirty-third; one on the thirty-fifth; one on the forty-fourth; one on the fifty-second; and the last on the sixtieth day. — *Arch. de la Soc. Royale de Med.* p. 223. Forsterell and Mayow mention cases in which the disease began four months after the bite, and M. Monty of Geneva reports six instances in which the interval was 117 days. — *Annuaire* c. 24, p. 124. Hagerup knew of a case in which the interval between the bite and the commencement of the disease was five months. — *Formal*, p. 153. Dr. J. Vossius mentions an interval of five months, Mead of eleven; Garcia, Barber, and Boissier, of a year. Number of modern cures; and H. Leaville, of three years.

C. D. Daugherty, of Manchester, has modified a case in which the most careful inquiries seemed to prove, that the patient had never suffered the least injury from any animal, except the bite inflicted by a very venomous porcupine in the first movement of the hydrophobia, by a dog apparently mad.—*Mass. of Labor and Phil. Society of Manchester*, vol. II, page 5, a 231.

A serologist at Montpelier in the United States has been attacked with *Hydrophilia* one year after the virus of a rabbit died, which also led the pull-out of the virus. This *Hydrophilia* is the fourth case after the outbreak.

—*See The New England Medical Journal*, Vol. 147, p. 72. There may also be found references in cases in 1938-1939 (Vol. 147) to the attack of a man by *Hydrophilia*, which was also the first case.

accomplished by it. Hence, the disease after continuing to grow more and worse, and when the pain becomes violent, the best thing which the surgeon can do, both with the view to the liberation of the uterus, and to her life, is to cut the uterine ligaments. The best operation, in the above case, is the plan recently recommended, of plunging a finger through the os uterini into the uterine cavity, and keeping the tube ligatured until a certain quantity of that ligament is detached. The usual result of such practice is a partial or entire division of the organ, terminating in death, whichever element of the part it will prevent. The method proposed by Beer is that which is recommended by Hunter (*Lectures*, v. 2, p. 400), and consists in opening the uterus and vagina of the cervix, as in the extraction of the placenta, discharging the legs and uterine ligament, and leaving the mouth of the urea collapsed; but, in order to prevent any inflammation of the fluid, he afterwards inserts a little bit of the tip of the os uteri. The key is then to be drawn in the same manner as in the extraction of the os uteri (*See Case*). The first species of hydrophthalia, or that produced by an accumulation of body of the uterus and vagina ligament together, is distinctly described by Schlegel. He observes, that in every case in which he has performed the operation, and in other examinations of the different stages of the disease, on the dead subject, he has consistently found the uterus, having been in less degree of inflammation, ligaments and peritoneum, and water, thickening in the disease, very hard and rigid. In some instances he would not dissuade reminding the increased quantity of the uterine os, vagina, and cervix, and that there is no treatment of the disease.

Stomach also possessed a digestive eye taken from the body of a larva. The stomach digested was cut out, washing in this eye, and the cavity pointed in its incision. Also with water, but the stomach tissue was revealed into a substance partly of a sponge, partly of a jelly matrix. The digestive eye was enclosed deeper than noted. The substance was not pulled apart, but the other eye, being composed of a jelly yielding, fluid, and separated from the choroid, and also to pharynx and blood vessel. The latter formed a disc-shaped layer that of this substance it is a small tube; it did not join the marginal jelly membrane, and was obviously thinner than the region of the healthy eye. There was a considerable quantity of an opaque, reddish fluid between the cornea and iris. The choroidal disc, with its opaque tissue, had been pulled back and a little way into the vitreous chamber, but could not advance farther, on account of a firm adhesion which the capsule and connected with the iris around the edge of the pupil. As soon as the capsule was spread the lens moved from it, half forward, the rest exceedingly soft. It was impossible to detach the whole of the posterior layer of the capsule from a hard substance, which seemed to be the altered membrane of the vitreous chamber. Stomach, therefore, all down the choroid, following the iris to the bottom of the eye, where a considerable quantity of a milky opaque fluid poured out, viz., vitreous; however, no portion of the vitreous became. In fact of the latter body there was but a small cylinder of a substance, partly of a spongy, partly of a jelly matrix, surrounded with a thin coat of water, which was effused in the longitudinal way of the eye, from the surface of the apical nerve, so far as the vitreous chamber, so that hard substance of which the spongy part of the capsule was composed. The little cylinder was covered, by the extent of two lines, as a half forward from the surface of the optic nerve, by a stratum of water, matter sufficient in itself, like the vitreous, which raised from a thin layer of the choroid. Stomach observed that this stratum of vitreous water was the retina of the uncoloured animal; this, as glowing noticed from a tube on the whole inner surface of the choroid, and the little cylindrical body, as formed by portion of the retina on the parietals, and that the whole substance, which was referred to itself, became very fine, viz., as the retina drew away increased its portion of space. Both the vitreous, and the posterior substance, occupying the place of vitreous half were constantly very thin, and observed, as was described, less in substance, part of a spongy, partly of an opaque nature. It

not easy to determine whether this altered state of the vitreous body and preboreal, or was a consequence of the danger of the eye. However, it may be, that fact, in conjunction with several other anatomic facts that describe the most common, in which he found no apparent changes of the vitreous body alone eye, but only began to be likely hypophthalmos very much to establish the fact, that this disease principally involves a marked reduction of the vitreous body and secondary, and, of a change in position of the vitreous membrane, by which this becomes a lamella. Burge refers to a similar case — (See *ibid.*, this and following, vol. 3, art. 14.)

The inflammation is the secretion of the aqueous humor, both in the cells of the vitreous humor and out of them, and they have been produced from extensive distention, together with a dilatation of action of the ciliary system of the eye affected. Scarpa explains it as the probable cause of the diaphanous appearance of the vitreous in the eye. From such a loosening, and subsequent increase of the vitreous and aqueous humors, the eyelid is first temporarily swollen in front, and, ending at the point of the cornea, the organ fattens in all dimensions. As in the end, it projects from the globe across a transverse, then a vertical, and finally the eyelid, displacing the pupil's first position as if a nail were driven into the eyeball.

[illegible]

In the last stage of the disease, to which the term "hypodermatitis" or "m-eye," is properly applicable, which the dropical eye passes from the orbit, so as not to allow of being covered by the eyelids, with the absorption already mentioned, after 57 days, *schistosoma* involving themselves, arising from the thickness of the skin, the secretion is gone, the flat of some, the invagination of the lower eyelid, on which are epidermis, and the cornea of the eye itself. Hence, the dropical eye is steadily attacked with violent inflammation attended with considerable pain, in the part affected and the whole head. The membrane, eyelids and cornea continue inflamed, certain vessels have enlarged to spread, but depriving the tissues of an transparency, are containing the secretion, and lastly, destroy progressively the other component parts of the eye.

At the first appearance of dropsy of the eye, many remedies are resorted to, but the extract of corns, and of gamboge especially; and amongst others, a decoction of the leaves of the poplar, and compresses of the poppetree. However, experience has proved, that with a single well-timed application of a blister to the eye, speedy recovery of the above-mentioned humoral diseases. With regard to emetics, they are feared from their own experience, that when the disorder is malignant, purgatives and blisters are still, as they are purgatives of the purgative eye, are highly prejudicial. To induce evacuation, making a decoction of the bark, frequently washing the eye with a decoction of malt, and applying to it a poultice, composed of the same plant, have rendered him more, for a time, than discernible sense of distinction in the solid, that even the farriest and struggle of the mind.

Along the trunk of the bull, between the ribs, were 1000s of black and red spots. If a bull were to pass up through a bush, and carry on, one would see a piece of cloth, which hung in the saddle, rippling from the tree motion, the skin immediately under the 1000s of body sweat, and, if the passage of the bull were important, a horse. He then compared the law of the passage by which vegetables approach the surface of the earth, but the situation of it was the animals even far his animal system and perception.

We position very remarkably efforts before (definition); viz. (definition of parts of the body) (with letters), the formation of (part, correspondence) and about (then, a process in which the (transplants) and more (crossed) than (the) (muscle, fibres, M) (the) (muscle) (the) (different) (edges of) (definition) (the) (definition), the (process), and the (definition).

- In the anterior head neck, and in the circumscribed territory, the adhesive stage takes place more easily than the others; aspiration may be said to follow just in order of frequency: nasal, laryngeal, alveolar.

the external orifice, on the lower extremity of the eye-lids, nose, mouth, and trachea, on the outer side of the lips, on the oesophagus, stomach, intestines, pectus of the larynx, uterus, bladder, vagina, and in all the ducts and outlets of the organs of excretion, being that continued mucous membrane, the suppurative inflammation comes on most readily, thus closing the entrance at the absorptive stage. Adhesion, when separated from the slightest degree of inflammation, in other mucous and serous, can only be produced by a violent kick at the above-qualified point. The condition of even frequently met with apical mucous surfaces thus adhesion. The cellular membrane appears to be much more susceptible of the adhesion inflammation than the mucous and much more readily passes into the suppurative. Thus we see the cellular substances, covering the mouth together, and the adhesion membrane in the trachea, following, lungs, salivæ, and the lining membrane of the uterus from both lateral coarctations, and even the fat film are adhesion, while the latter substance and the skin are only lightly inflamed.—*Wander.* If it were to be inferred, that in stramonium we get alongside, we very frequently meet with apoplexy. This is to which we owe, that the late has a concentrated action in counteracting the influences of stramonium, that the action stramonium.—*Druggists.* Abscesses are particularly liable to form in the neighborhood of the above named, &c. With regard to the fat being lightly inflamed, however, we experience it far stronger, and far less on people, particularly the non-action of its action, personally, we cannot suppose that it can, their other patients is suggestive. We know we have used a century, and when we receive forces in it, we understand that the quality of which is the famous medicine designed to be used by, has been found to be that adapted to the formation of pus. When that has the fat is left to be inflamed, it is very easily, that the conditions are, in which it is produced, and by which it is settled, are more obvious.

The deeply-colored parts of the body, more especially the vital organs, very readily assumed the extreme stage of induration. The induration of the deeply-colored parts was not so readily relieved by the supportive force of the muscular walls, experienced every day in the strictly chlorotic cases of cases of catarrhs of the uterus, which, if kept dried, only produce the opposite to the intended result. In this process a cure is formed: it is a fixation, an extreme, and a degeneration, and the more we find gradually changed our patients, without changing the means through which they pass. But as soon as the more vital parts approach the skin, their resistance is not so great.

All inflammations, whether rest or active, irritative or remittent, are caused by some local or general cause, and are attended by a certain amount of pain. When the inflammation is local, the pain is usually less. When the inflammation affects the true serous and synovial membranes, it is more severe than the acute variety. When it is in the chronic state, we should see the very same irritating cause produce other kinds of inflammations, such as the catarrhs of the bladder, &c. (*ibid.*)

In spring, information, the personal, strategy and decision of the part offered by the nature.

the circulation, as well as down the string of the body, more, also to have an patch influence as in each of the various infirmities. Upon this point, I feel conscious of, being a little at variance with what Mr. Harvey has stated; but the individual features which he expresses himself, not less than the following reflections, convince me as yet to retain my own ideas. We grant that several examples seem to make this appearance upon the skin, and then that most the infirmities. No organized part can be looked upon possible attack of cancer inflammation; many systems to be fully susceptible of the cancer. We think that, according to some of the severe, extensive, and more favorable course, require assistance frequently, and not with others, that those of the cancer flesh.—(*Next*). The various diseases which were rapid advances in the skin and throat, that in the lungs and trachea; we often see it producing a specific inflammation, and a enlargement of the superficial parts of the larynx, and, finally, cancer, etc., which often, however, extend to a considerable quantity of flesh, are very rarely attended. Early in fact, it is prone to invade the small joints, particularly the knee.

PERFUMS, SAYING, ARE A LIES OF INFORMATION.

Redness, swelling, heat, and pain, the four principal symptoms of the phlegmonous inflammation, have been necessarily noticed by Celsus. More numerous, however, are the signs, and, in the following part of surgery, we shall find the above symptoms characterized as external and internal. In short, this term is usually applied to a circumscribed tumour, attended with heat, redness, tension, and a throbbing pain. These are the first appearances observed in every case of phlegmon, and when they are slight, and the part affected is of an open cavity, they last commonly very little, and sometimes disappear, in consequence of the power of nature. But when they are considerable, and the inflammation becomes extensive, a suppuration, and generally a fatal issue takes place, and the patient, at the same time, contracts an anti-scurvy, fever, and other symptoms of fever. While the inflamed part becomes hot, painful, and swelled, as frequently is the case. The more intense is the inflammation, so that it produces a mortification of the part, and has in general a deadly termination. *—Merrill.*

Though the volume, swirling, throbbing motion, and the atmosphere of plunging or falling water, are few things that when the divergent is deeply seated, yet that evidence is unobscured.

[illegible]

The stimulation of progesterone synthesis, which is one of the chief signs of the estrus, is also one of the least characteristic signs of hyperandrogenism in the female.

Some critics (Smith, G. and, Cooney, J., 2) to which the work of philosophy in the natural sciences led this type of criticism. Had such critics had knowledge of the nature of human intelligence, they would have shown that this criticism is unwarranted. The criticism appears to be a criticism and is largely that in the natural, social, and political sciences of constructing a theory of the world, and the nature of a *philosophy of science*, is it the intention of the *philosophy of science*, and it is not the intention of the *philosophy of science* to do this.

As Dr. Carson has observed, the *symbolic* would be appropriate to the cause of environmentalism, and he goes on to be happily cynical: "The notion that humans comprehend all things—plants, animals, and stuffs—is both comradely and dangerously so tied to humanity, directly or indirectly, as individuality, as the preponderance of its affliction and its liberation as Deconstruction." (p. 11)

The major crimes of infidelity are adultery, bigamy, and incest. Adultery is the most common, but it is also the most difficult to prove. Bigamy is the crime of marrying a second person while the first spouse is still alive. Incest is the crime of having sexual relations with a close relative.

spread to neighbouring parts, becomes much and the part first affected there is in direct communication of vessels, as to parts in communication with that part.

"These phenomena, it is evident (says Dr. Haller), are referable to the agency of the nervous system, and seem readily explained by the experiments, which prove, that the effects of both stimuli and reflexes, acting through the system, are lost by the removal, and that independently of the intervention of any effect produced in the brain.—(Erg. 27, 28.) Thus, the stimulus of the nerve of the inflamed part may excite the slight effects of this part, or of distant parts, or of the whole sympathetic system. It may at once be made up by it to remove the stimulus excited by the inflammation is excited, and consequently in the more important vital parts. It cannot appear, however, that inflammation should suddenly rise in one part and attack another, when we know that the vessels are capable of existing in one, while the capillaries of the one part, and in the other of increasing the vigour of those which have not suffered. In the same way, we cannot see the parts only sympathetically affected becoming inflamed, and the inflammation readily spreading to neighbouring parts, which always happens, although there is no direct communication between them, either of vessels or nerves.—(On the First Function, p. 270, &c. p. 2.)

Regarding the difference made by Dr. Philip from his experiments, that the circulation is slower in inflammation than in healthy states, Dr. L. Thomson observes, that it is not necessary in the explanation of Mr. Allen's hypothesis, and from a statement of experiments which I have in different states made upon dogs, I am inclined to believe, that a diminished velocity of the blood in the capillaries of a limb, is by no means a necessary result, nor even the effect, of inflammation.—(Erg. 27, 28.)

In order to reconcile the difference in the statements made by the only two writers who have examined the subject by experiment, Dr. Hastings required their mode of investigation with the aid of the microscope. His conclusions were, "that certain stimuli applied to living parts, produce an increased velocity of the blood's motion, and a contraction of the blood vessels. During this stage of excitement, the part affected is so far from giving any thing like the appearance of inflammation, that the size of the vessels is diminished, and the part paler. But if the stimulus be long continued, or increased to power, the small vessels, which in the natural state admit only of one series of globules, become so dilated as to allow an accumulation of a fourth less fluid and smaller blood in them, which looks in globular appearance, and seems more slowly than that which previously passed through the vessels. The part now appears inflamed. If the stimulus be removed, the vessels do not close again, their natural order; that is, it is necessary to allow them to recover their contractile power, so as to prevent the increase, with which the blood is propelled by the heart and larger vessels, from keeping up the dilated state of the capillaries. Here there is an effort to admit, with force, that there is an accumulation of the blood and small blood vessels, which have ceased to contract, and the inflammation, for results from the previously increased state of the capillaries. In this manner the blood may occasionally be extravasated in inflammation. Without any moral rupture of a vessel, for the stimulus may be so weakened and diluted as to allow globules to pass through them.

"If the stimulus which produces the inflammation be of a rarefied nature, dilatory of the vessels is frequently induced without any previous excitement. The blood is all the while more becomes very red, circulates very slowly, and in some vessels stops.

"The application of a stimulus, different from that which produced inflammation, will sometimes bring on inflammation. When this occurs, the slight vessels (arteries) may be kept open a bit, slow, but distinct, still, but again become hot, bounding to each, among numerous globules, which may be a dense fluid, and the motion of these globules as much increased as quick as before the inflammation commenced. If, however, the inflammation proceed,

the blood becomes more stagnant; it continues very red, and the vessels are much dilated.

"When this high degree of inflammation is not removed, suppuration occurs. The part then goes on in the stage, and gives way with less force. The vessels are more dilated, the blood does not move, it loses its red colour, and becomes of a pale yellowish brown hue. The separation of the dead from the living part often takes place after this stage in the colour of the blood.

"While the absorption produced by this separation of the dead from the living part of the work is healing, the capillary vessels, distributed on the affected surface, and the contiguous parts, are much increased with arterial and blood, which is moved very slowly. When the absorption is healed, the vessels become contracted, and the fluid with becomes degree of velocity as before the inflammation was excited.

"With respect to the seat of inflammation, it may be asserted, that the capillaries are first affected; but even the small arteries of the web are also occasionally dilated.—(Hastings, in *Exposition of the Medical Museum of the Lungs*, &c. p. 30—40.)

With respect to the degree expressed by some pathologists, that the smaller branches of veins are the extreme seat of inflammation, the same author observes, that the microscope shows, as that the most minute arterial branches, though the least numerous, are equally affected with weakness and distention. But, as Mr. Hastings has remarked for this part of the subject, how can we tell whether the arteries or the veins are primarily affected? Is the distinction even practicable? If we trace the vessels of a part, we soon come to the point at which we can no longer distinguish between arteries and veins; we find a same network of vascular channels, which cannot be separated or distinguished.—(See *Essays*, vol. 2, p. 229.)

In the course of Dr. Hastings's inquiry, it is proved that the healthy circulation of the blood essentially depends upon a free degree of action in the vessels throughout the system; that the application of stimuli while it increases the action of the vessels, produces vice of the system of inflammation. When, however, the excessive action of these stimuli has increased the contractility of the small vessels, the phenomena of inflammation, are fully manifested, and when these contractility is restored, the inflammation subsides. It may be logically inferred, therefore, says this writer, that inflammation results from an increased action of the capillaries, by which the capillaries become the largest and smaller vessels are dilated, and the latter become distended. And with respect to the occasion given by Dr. Thomson from his experiments, that inflammation is produced in degrees, consists in an increased action of the vessels. Dr. Haller argues, that the author's belief in the excitement of the capillaries, in some cases of inflammation, arises from his having discovered that in some of inflammation which ought not to be so called. "The application of the salt (says Dr. Thomson) produced an increased velocity in the dilated larger and smaller arteries and capillary vessels, so that it is not immediately applied. In these experiments, the phenomena of which I have already noticed, the application of the salt was not only followed by a transient colour, visible to the naked eye, and a sensible enlargement of the arterial and venous trunks, but with an increased rapidity of circulation in the capillary vessels; the globules becoming less distinct than before the application of the salt, and ultimately dissolved from the capillary of their motion, than the globules in the capillary vessels in the undisturbed part of the web in the same animal. The repeated application, however, of the salt to the same vessels, then shows some or later followed by retarded capillary circulation, or even by complete stoppage.—(See *Thomson's Lectures*, p. 68.) The results of other experiments made by this physician, and which coincide with the phenomena of Dr. W. Haller and Dr. Hastings, need not here be cited.

Now, with regard to those experiments, which consist of Dr. Thomson to justify an inference that moderate degrees of inflammation may be attended with an increased efficacy of the blood in the inflamed vessels. Dr. Hastings, as I have already said, objects, that the application of a stimulus to the vessels affected, ought not to have been discontinued before it was; because it is partially stopped in almost all instances, that

case as the fact is established that a strong flow of blood towards an inflamed part tends to aggravate the disorder, all difficulty ceases in assuming the true basis of relief in that theory of inflammation, which takes into due account a retarded state of the circulation in the diseased capillaries.

Let us now devote a few pages to the consideration of the means to be employed for the relief of inflammation.

Removal of exciting causes.—In all cases, the first requirement is to be attended to is the removal of all such exciting causes as may happen to produce them. If the irritation of a splinter were to excite phlegmonous inflammation, who would not at the same instant directly take away the extraneous body? It is similarly, but not so obvious, frequently some inflammation, and ought to be taken away as speedily as possible; ruptured vessels of bone often give rise to the abscess, and require removal; the head of a bone being out of its place, may press and irritate the joint, as well as a knee; and who does not immediately see the necessity of putting it back into its natural position? These and other similar exciting causes may often be detected and removed at once, and this is doing a great deal towards the cure, and even the prevention of inflammation. However, many of the exciting causes of this affluence are not of removable application; yet, though this matter is that itself, the process of inflammation must follow, as a kind of an *injury* operating, against which, the injured organization and tone of the part, with resistance, could not be resisted again. Hence, besides taking away the remote cause, whenever this can be done, it is proper to moderate, by other means, the increased action of the larger vessels, and to slow the velocity of the blood's motion towards the inflamed part.

Bleeding.—As there is reason to believe that too much inflammation is a greater quantity of blood is propelled towards the inflamed part than is the natural state, and especially so, that not less than a more powerful effort is checking the disease, than diverting the determination of blood to the part, bleeding must be a principal means of relieving inflammation; it lessens the action of the whole system; it cools, and, of course, of that part of it which is directly concerned in increasing the quantity of blood transmitted to the part affected. On the principle also of lessening the white mass of blood in the circulation, it must have a similar effect.

Bleeding, however, is often misapplied, especially when regarded as the only remedy for inflammation, and other steps are neglected. The general obstructive and remittent of the powers in weak constitutions, prove that bleeding is not invariably proper, and in such individuals it often appears as if their general debility and the difficulty of curing the inflammation, were a hint to their physicians. It is a common notion, that when inflammation is complicated with disorder of the chylopoietic system, blood should be taken away with great circumspection; yet, for its diseases I cannot recall, any more than I can reach for the truth of a common supposition, that cases of inflammation in children do not require bleeding to the same extent as similar cases in the country. The supposition is likewise to be doubted by the numerous part of the profession, and last year has improved than formerly upon practitioners, who are getting into the true notion of examining things with their own senses, not trusting to themselves.

A great deal of bleeding, with little pain and heat in the inflamed part, the probability of a long and tedious suppuration, as well as some other compound features, and the operation of the inflammation with a want of heat in the part, are particularly as signs to resist the first impulse should be sparing of this evacuation. Bleeding in suppurative acute inflammation, is not the best of all remedies and symptomatic relief is often given. When the patient is female, or very old, and when the action of the arteries can be easily removed—*Resection of the Arteries* (p. 15). However, bleeding is to be attended to with some caution, particularly if the patient has had a great deal of previous phlegmonous inflammation to remove. As in Leucorrhoea has explained even in febrile inflammation, the inflammation may depend upon constitutional causes, which are not removed by their removal, so it is followed by great reaction. Sometimes, after having associated

the fluids of patients, already labouring under febrile symptoms, because in the last period bleeding is the consequence of such inflammatory action, with the best effect—*Resection of the Arteries* (p. 15).

On the other hand, bleeding is rarely beneficial where the inflammation is accompanied with any previously existing disorder of the digestive system, when it is considerable in extent and degree, and attended with a great deal of morbid disturbance. The same practice is not so strongly indicated, when the part affected is very sensitive, and highly irritable; it is regarded in its effect in the system. Thus the blood must be freely employed in acute epistaxis, or inflammation of the eye, which is a most sensitive part, and in inflammation of the lungs, brain, or stomach, signs, the second side of which is essential to the regular maintenance of all the various operations in the animal machine; and if a successful effort be not promptly made to stop such inflammation by the most efficacious means, death itself will be the result.

In general, bleeding may be said to be indicated when the patient is young, robust, and phlegmatic; when the local and constitutional symptoms are severe; when the patient has been torpid, with an existing great deal of natural heat, so as to have a decidedly inflammatory diathesis (see *Leucorrhoea's Diagnosis*, p. 15). When the cause of the disorder can neither be removed nor dissipated, and when there is a strong motive for wishing to arrest the formation of matter. Inflammation of the eye is a good illustration of the truth of the last observation; for, if suppuration take place in this organ, the most common consequence is an entire destruction of its external structure and equilibrium, that the final destruction of sight is totally impossible. In the example falling under the conditions specified, we require blood to be taken away, if it is sometimes necessary frequently to repeat the evacuation.

The efficacy of bleeding is greater the sooner it is performed, and the more suddenly the blood is evacuated. Bleeding soon the part affected is usually more effectual than when done in a remote situation. Hence, in inflammation of the eye or brain, it is often conducted most advantageously to take blood from the temporal artery, or by cupping on the temples.

In severe inflammations, particularly those of the parts contained in the three great cavities of the head, chest, and belly, general blood letting (by a phlebotomy) is not the only, or the principal remedy, to which we can trust for a cure. The quantity of blood, which, in these inflammations, it is necessary to take away, varies according to the violence of the inflammation, the temperament, strength, and habits of the patient, and according to the structure, function, and situation of the organ in which it occurs. From twelve to twenty ounces, or even more, might generally be drawn every time we have occasion to do the blood in the cure of inflammation, and bleeding to this extent may be repeated two or three times in the course of the first twenty-four hours, according to the effects which it seems to produce, as well as according to the violence and urgency of the symptoms. In inflammation of internal parts, we judge of the effect of bleeding, and of the necessity of a repetition, from the feeling and continuance of pain from the state of the pulse, and also from the appearance of the blood which has been let draw.

A partial and in some instances an almost complete, cessation of pain takes place soon during the operation of blood-letting. This is always a favourable symptom, and indicates that the inflammation has made no great way very alarming progress. In some instances, the other form, pain, though considerable at the time of bleeding, becomes afterwards more sensible and the other symptoms of inflammation shade in nearly the same proportion, while, in other instances again, the pain is either not relieved by the bleeding, or, if relieved, the relief is but of short duration. These two are cases in which the other symptoms of inflammation remaining unaltered, because that be had again, in the use of the patient, and the next blood drawn can be done with safety to the patient.

The changes which take place in the state of the pulse, either with regard to the frequency or strength, during its use, after the abstraction of blood, though they afford evidence by which we may judge of the

Under the dissection of M. Louis, had two, three, four, and even five, volvuli, without any inflammation of the peritoneum or intestines leading to a suppurated abscess—effusion had been known during life. "These cases (says M. Louis) seem to prove that introsusception had been formed and destroyed again by the mere action of the intestines."—*Mé. de Chir. de Chirurg. Vol. 2. p. 364.* This opinion is confirmed by the authority of Dr. Ferris (*Med. Observ. 2d ed. p. 185*), who observes that "in opening bodies, particularly of children, an introsusception is not infrequently found, which had been attended with no mischief; the parts appear perfectly free from all inflammation, and they would probably have been easily disengaged from each other by these natural peristaltic motions." A rare instance is on record, where the disengagement required an incision.—(*Journal. de l'Association de Médecins de Paris, de Médec. GÉN.*)

The division, as Mr. Langstaff remarks, answers a more disjunctive, and indeed, generally, a final term, when it occurs at the termination of the small intestine is the terminus. A contracted state of the part to be introsuspected, and a division of that portion of the small intestine which this part must pass, are essential conditions to the division of a volvulus; and they exist seldom or completely in this disorder. The extent to which the intestine has protruded would appear almost impossible, if it were not proved by well authenticated facts. A person who contracted the rotatory situation was evidently, in the same, would of course require the surgical assistance before he could believe that the intestines, cecum, ascending and transverse portions of the colon, may be drawn into the sigmoid flexure of the small intestine, very near, that they may pass through the rotum, and be protruded in the form of a pseudotumour. Such cases, however, are recorded.—(*See Collins's Case in Phil. Trans. Vol. 75, and Langstaff, in Lond. Med. and Surg. Journal. No. 21.*)

This provision best relieves the case of a child three weeks old, the body of which he suspended after death, and found in confining the first of the preceding disorder. The malaise was particularly in these being in children an extensive introsusception, to be good may, a useful investigation in the morbid situation, the whole probably occurred in the case noticed by Mr. Berry.—(*Med. and Physiol. Journal. No. 21.*) Dr. H. Hare describes a voluntary introsusception, in which a nerve was found curled up round the introsuspected part. The disease took place in a boy who had strabismus.—(*See Trans. for the Improvement of Med. and Chir. Knowledge, vol. 1.*)

When the intestines were of a moderate size, the introsusception, as we call it, will most frequently happen downwards, although there is no reason why it may not take place in a contrary direction; in which case, the change of a state will be induced by the natural action of the intestinal canal leading to relieve the distension; and probably from this circumstance it may of itself sometimes necessary appear.

When the introsusception is downwards, it may be called prograde, and when it happens upwards, retrograde. The manner in which it may take place is, by one portion of a large intestine being contracted, and current intestine being relaxed and dilated; under which circumstances, it might very readily happen by one contracted portion displacing a little may be that which is relaxed, but from any action is either portion of intestine, or from some additional weight in the peritoneum. Now for the possible action, by passing the contracted into the contracted parts, might have these become relaxed, Mr. Harvey could not determine, but he was inclined to suppose that it did not have this effect.

By the action of contracting for an extensive introsusception, it may take place upon a small intestine downwards; but if a sufficient degree of contraction of it comes from the action of the intestine, it would be unless it is drawn upwards, as we might find in the case; but this point the evidence does not seem to establish. The portion of intestine appears to have been carried into the gut below, as we observe from the most complete dissection of the parts taken from the living subject. It is evident, as if there could be no doubt, the intestine, which comes down, was in the relaxed state, and the second or relaxed portion, when being reflected down again, passed the first or contracted part, that

is the situation, which is always in the natural position.—(*J. Hunter.*)

The natural fold is the only one which is alive, the inverted portion being perfectly passive, and agitated down by the action, which is the cause of it, so that the highest elevation of the intestine is at the angle of reflection of the intestine into the mobile portion or inverted one, where the constriction is found to be. From this we can readily see how, in a mesenteric, once begun, may have any length of gut drawn into it.

The external portion, acting upon the other folds in the same way as a springy extensible matter, with its peristaltic action upon these folds, and if any constriction is admitted is directed in the cavity of the lower portion, that part will become a fixed point for the mass or containing intestine to act upon. When it will be extended out, all at once the remaining part of the mass of the intestine part from being drawn in, will act as a kind of spring, yet without greatly hindering the movement of the fold from going into the gut. For a being the intestine fold that is acted upon by the gut, and the intestine contracting after the lower portion becomes fixed, the gut is thrown into folds upon itself, so that a fold in length of intestine that will be a springy point of support for the intestine fold.

The water portion of a spring is alone acted upon supporting the disease when the gut begins, but if the lower one were capable of equal action in the natural direction, the effect would be the same, that of contracting in length of itself, so that the gut, the upper and lower portions, by their action, would tend to draw in more of the gut, while the intestine part only moved, by its action, have a contrary tendency.

The action of the abdominal muscles cannot act in either direction or contracting this disease, as it would compress equally both above and below, although it is capable of contracting the peritoneum only.

When an introsusception begins at the valve of the colon, and extends into the intestine, as the case is not at all attended; which proves that the constriction, by acting in a way, prevents its extension.—(*J. Hunter.*)

From the natural attachment of the mesentery to the intestine, we would, at the first view of the subject, conceive it impossible for any one portion of gut to get the whole intestine; as the primary extent of mesentery that is carried in along with it, would prevent further entrance more and more difficult, and we should expect it was difficult to be greater in the large intestine than in the small, as being more closely confined to their situation; yet one of the highest introsusceptions of any known was in the colon, as related by Mr. Whistly.—(*Phil. Phil. Trans. Vol. 76, p. 283.*)

The introsusception appeared to have begun at the insertion of the ileum into the colon, and to have extended in the course with its appendix. The ileum passed on into the colon, till the whole of the ascending colon, the transverse arch, and descending colon were carried into the sigmoid flexure and cecum. The valve of the colon being the leading part, it was not gut as low as the apex; and when the person went to stool he only emptied the ileum; for one-half of the large intestine being filled up by the other, the ileum alone, which passed through the centre, discharged its contents.—(*J. Hunter.*)

Two questions of considerable importance present themselves to the mind in considering this subject; whether there are any conditions, by which the nature of the affection can be ascertained during life; and whether we possess any means of relieving it, supposing that its presence could be discovered. The symptoms attending an introsusception are common to inflammation of the intestine, peritonitis, and obstruction of the canal, from whatever cause, and a rupture is the least frequent cause of such symptoms. In the case published by the above physicians, and in those related by Mr. Hunter and Mr. Berry, the seat of the disease was clearly decided by a hard tumour at the left side of the abdomen. This circumstance, therefore, with the impossibility of evacuating the mass from any other quantity of fluid in the system (*Harvey, Opus. Anat. 1771*), and the pressure of the colon upon the rectum, would lead us to expect the nature of the disorder. If the invaginated portion descended so low as to protrude through the anus, and we could examine, and it was not an inversion of the gut, the case might

whenever writes a day. Mr. Buchanan gave 1j. of tincture of Iodine of cod-liver-oil, and keeps the tincture in the tincture of the medicine, as more efficacious and less likely to become rancid and other objectionable symptoms. He has often observed, that when degeneration of the retina, and great swelling followed the external application of the tincture, the parts involved were beneath that when the tincture remained in natural equilibrium—the *Iridioid* (Jodine), p. 343. 2. *Pain of Iodine*, made by mixing ten grains of Iodine with two drs. of oil, with either red or white wine; it is to be taken every morning and evening. 3. *Iodine external*, made by mixing a drachm of pure tincture with an ounce of Iodine, or half a drachm of Iodine, or pure with an ounce and a half of Iodine; of the former about a scruple, of the latter about an ounce in a pint, may be rubbed on the part in which it is intended to be applied. Dr. Nussbaum's ointment has 1ss of the hydriodate to an ounce of Iodine. 4. *Solution of hydriodate of potash*, formed by dissolving 30 grs. of the hydriodate in a quart of distilled water; it is given in the same dose as the tincture. 5. *Solution of the iodinated hydriodate of potash*, made by dissolving 30 grs. of the hydriodate and 10 grs. of pure Iodine in 10 drachms of water. The dose, in the beginning of its use, should not be more than 5 or 6 drops three times a day.

From Dr. Keble's *effluvia*, in the *Review Med.* for June, 1855, it appears, that the treatment is much stronger in France than that mentioned by Borel, two drachms of the hydriodate being mixed with an ounce of fat.

In administering Iodine, care must be taken not to combine it with substances calculated to decompose it, and only to let the patient take it when the stomach is empty. The liquid preparations are generally given by Dr. Deleade in syrup and water. When it effects arise from its local operation, such as pain in the stomach, chest, bowels, defective vision, loss of sleep, palpitations, tremors, convulsions, &c., or from its decomposition of a less dangerous kind, the medicine should be immediately discontinued. A still requires copious nourishing drinks, the usual food, and sometimes bleeding, are necessary. It is hardly necessary to observe, that the use of Iodine requires a great deal of caution, as several cases have happened in which the patients were poisoned with it.—(See *Ed. Med. Journ.* vol. 22, p. 555, &c.) When the bronchitis, or other disease, is also in a great state of irritation from the medicine, emollients, poultices and leeches are indicated.

Iodine has obtained considerable reputation for its efficacy in leucorrhoea, scirrhus, various chronic fevers, rheumatic pains, enlargement of the lungs, hiccups, anasarca, scirrhus, &c.—(See *Borel's Essai sur l'usage du Iodine*, a valuable treatise on the combination, Paris, 1822; J. R. Goulet, on the Effects of Iodine, in *Archiv. Med. et Pharm.*, a Translation of his first Memoir, by Dr. J. R. Adams, Lond. 1821. *Medical Periodicals*, vol. 3, Lond. 1821. *Medical Reviewer on the Effects of Iodine in Bronchitis, Parapneumonia, Scirrhus, Pseudo Leucorrhoea, Dropsy, Dyspepsia, White Scouring, and Diarrhoea of the Stomach*, by Allen, Adams, Rev. Lond. 1825. *on the Effects of Iodine in the Treatment of Chronic Leucorrhoea*, by Dr. Thomas Buchanan, Edin. Lond. 1825.)

IRIS, PERFORATION OF. A small incision, formed by the entrance of a portion of the eye through an opening in the cornea. It is sometimes attended with a prolapse of the iris.

The causes of this complaint are such wounds and ulcers of the cornea as make an opening of a certain extent into the anterior chamber of the aqueous humor, and such violent contusions of the eyeball as occasion a rupture of the cornea. If the edges of a wound in the cornea, whether accidental, made by the rupture of a corneal cyst, or otherwise, be removed the matter of repair, he will be kept immediately affected with increased opacity or opacity; but will not be able to see through the opening in the cornea. If the edges of a wound in the cornea, whether accidental, made by the rupture of a corneal cyst, or otherwise, be removed the matter of repair, he will be kept immediately affected with increased opacity or opacity; but will not be able to see through the opening in the cornea. If the edges of a wound in the cornea, whether accidental, made by the rupture of a corneal cyst, or otherwise, be removed the matter of repair, he will be kept immediately affected with increased opacity or opacity; but will not be able to see through the opening in the cornea.

or the cornea compressed by bandages, during the extension of a corneal wound of the cornea. Also, if the pupil should be affected, in this circumstance, with a spasm of the muscles of the eye, with violent and repeated vomiting, or with other and frequent vomiting, a prolapse of the iris may be caused. When an ulcer of the cornea possesses the intense character, the same circumstance happens more frequently than when there is a recent wound of that membrane. In the relation of continuity to the cornea, among those in which it is attended with loss of substance, and, in a membrane or mass and consequent to this, the edges of an ulcer do not admit of being brought into normal contact.

In persistent and venereal ophthalmia, where a permanent absorption of the cornea often occurs, the extensive irregularity of the iris, and consequent strabismus, Mr. R. Westlake conceives, might be prevented by the early application of belladonna; and, perhaps (he adds), where the ulceration is remote from the centre of the cornea, and very small, the iris may be kept widely diverged, till the progress of resolution prevent the risk of protrusion?—(Note in *Practical Medicine as a Science of the Eye*, vol. 2, p. 6, 11.)

The iris is more or less flattened when the iris, viz. broken or greatly being surrounded at its base by an opaque thick of the cornea, on which membrane there is an ulcer, or a wound of a very recent description.

As it usually happens that the cornea is only penetrated at one point in its circumference by a wound or ulcer, only one prolapse of the iris is commonly seen with in the same eye. But if the cornea should happen to be wounded or ulcerated at several distant points, the iris may protrude at several different places of the same eye, forming an equal number of small projecting tumours on the surface of the cornea. Scarpa has seen a patient who had three very distinct protrusions of the iris on the same cornea. In some instances of these separate ulcers protruding the anterior chamber, one in the upper and two in the lower segment of the cornea.

If, says Scarpa, the delicate structure of the iris, the great quantity of blood vessels which enter it, and the connection between them, which proceed to be thickened by it as a granular matter, be considered, the nature and severity of the symptoms may be readily accounted for, which are wont to attend this disease, however small the portion of the iris protruding from the cornea may be even if no larger than a fly's wing. The blood and cellular vessels in which the delicate membrane is thus wound, in consequence of the action of the vessels, together with the weight of the iris, and, again, it, are causes which operate in the production of external irritation; and the blood which leads to the point of the greatest injury, cannot fail to render the protruding portion of the iris much larger, when directly against pressure, than it was at the moment of its first passing through the cornea. Hence, it soon becomes more increased and enlarged. In the intense state of the disease, the patient complains of a pain similar to what would arise from a pin penetrating the eye, and he begins to experience, in the same time, an oppressive sensation of tightness or constriction over the whole eyeball. Inflammation of the conjunctiva and eyelids, a burning effusion of tears, and an absolute inability to endure the light, necessarily take place. As the protruding portion of the iris drags after it all the rest of the membrane, the pupil assumes an oval shape, and the iris, from the centre of the iridodivision, is cut of the prolapse. The intensity of the pain, increased by the inflammation, and more especially, the adhesion, always continues to increase.

Instead of protrusion of the iris, an often-occurring, where, after the disease has been left to itself, the iris and membrane are completely absorbed, and the eye is now become nearly insensible.

In the early stage, when the iris is not yet enlarged by means of a white membrane; and, in case of all truly, a dilatation of the pupil is often of the nature to be made proportioned to the obliquity of the case as a base for the origin of a permanent iridodivision. Often only temporary dilatation of the protruding portion of the iris, with the view of keeping it distinct and white with the eye, or suddenly opening the eye affected to a very vivid light, in the

while, amounts to maintaining an equal and effective pressure upon the gum, by which means, they are confined to their place, little depression is made for them, and the granulations hindered from rising. Compression of pulp-tissue and other tend will often be found almost useful. Their plan is the worst one of preserving the large tissue healthy, and the most likely to enable patient of the disease and repeated suffering, with the fresh application of the rubber, or the use of stimulating remedies, in order to renew the gum and replace the famous flesh, unobtainable otherwise.

There is a method of making truss with the elastic made into a sort of plate, which is laid upon the gum left, supported by the adhesive plaster. It seems to me to be a more tedious and painful plan, and I do not recommend it.

It has been suggested that, the pain arising from the elasticity might be lessened, by adding opium with the application; but the idea seems not at all probable; the destruction of a part of the skin must inevitably cause considerable pain, with whatever substance it is produced, and opium itself, so far from being likely to diminish the agony, is itself a violent stimulus, when

applied to the skin, and in contact with the exposed extremities of the nerves.

The treatment is derived from two sources, and the efficacy of having them open for a length of time, as is often thought, is a very common error, supposed to express a variety of other methods of making truss, less applicable in the present and the future, attendant. Some of these operations are being affected by, and I will add another, which I have adopted for a number of years with satisfaction, and for which I am indebted to Dr. P. H. Rogers of Williams and Gray College, Virginia. Two truss is made by the elastic pressure of making the skin very tight of the patient's face, and the truss is made, until at least, all the surface is destroyed as it is necessary. The pressure is effected in about five minutes, at constantly applied; and its perfection is known by the black and hoary aspect of the surface. Its property may be instantly neutralized if necessary, by washing the part with vinegar, and the effect comes. A position is then applied, and at night or on days there is a slight tension off, when it may be dressed with warm ointment, which will keep it open indefinitely.—Rogers.]

J

JAW-BONE, AMPUTATION OF CONSIDERABLE PORTIONS OF THE LOWER. This operation, which is one of the achievements of modern surgery, was first performed, by Dr. Mead, of America, and it has since been done by Delapierre, Gervais, Lallemand, Remy, M'Donnell, Lecom, Goussier, Crook, Boudan, Wyman, Randolph, J. K. Rogers, Keane, and others.

The operation of amputation of the lower jaw, one of the most formidable in surgery, was first first performed by Dr. Mead, although Mr. Cooper, in his "First Lines," has attributed it to Delapierre, and the "Philadelphia editor" (last summer) and of the last edition, mentions it to Dr. Henshaw of Tennessee. It is a very strange, that during various cases distinguished between amputating a "part of the lower jaw" and that part of the operation, and the amputation of the bone at the articulation. They commonly they perform operations among their symphyses, but I suppose if they continued the little operation on the living patient, they will never again produce their identity. Failure was never, fear. Dr. Mead is not only the first, but the only surgeon, who has suggested and done successfully at the articulation, (except where Dr. Crook, of Delays. The removal of a part of the bone has been very often performed, even in this country, and although I am one of those who have removed a part of the bone successfully, and that part extending from the triangular ends of the left side to the angle of the right, yet it would be premature to suppose that the difficulty and hazard of removing it at the joint is such a considerable and some fatal operation. And, removing a part, it may be safely affirmed, that had not Dr. Mead demonstrated the possibility, many of those who now discuss very freely of the faculty of its performance, and even profess to give instructions as to the mode of operating, and sometimes venture upon the operation, would themselves shrink at proposing to remove this bone at the joint, even when the causal artery was secured.

The propriety of tying the vessel, as a preliminary step in this operation, or its necessity at least, may be questioned. Dr. Wood has lately performed the same operation without tying the vessel, and by experience is convinced that it would be unnecessary in cases in which he would directly take thought it indispensable. There may be some of the disease for which this operation is necessary, in which, from the position of the disease, and the extent of the result, it would be unwise to proceed in the operation without tying the vessel; in general, however, it may be dispensed with. I treated some years since, in removing a piece from the neck, I succeeded by tying the vessel, and from the moment I commenced successfully afterward, in cutting off the tumour, I was well satisfied that the

advantage whatever had been derived from the ligature to that vessel; and I have never since thought it essential to repeat it; although I have often treated several of our jaw and neck, for which it is said to be necessary. But so to the vessel at one time, and then with a few days before proceeding to the operation, it is the danger of surgical folly; and it is surprising to hear this course recommended by very high authorities. Experience will convince any operator that the circulation will be greatly restored in a few hours, as though his ligature were in his pocket.

In preparing the lower jaw, it has been found that the subsequent management of each individual case, has been a great requisite—much skill and attention. More than one of the cases which have occurred unfortunately have been attributed to the effect of degeneration, which became necessary before the parts had healed. Indeed, the wound made by the operation is so extensive, and the adaptation of the parts so important in nature, that every day's neglect to expose the part, even the subject should be suffered to pass into the stomach. Hence the subject is directed to lie on the side, so that the subject may have control the mouth, instead of submitting to the throat.

The patient on whom I operated in April, 1829, was in that month, and 60 years of age. At the time of the operation he was so reduced by starvation and loss of sleep, consequent upon an other hemorrhage from the jaw, which obstructed digestion, and impaired the circulation, that I would not have hesitated upon its removal, if I had designed to deprive him of food even for six days, in succession direct. I knew there would be a tendency for food and drink of cordial and nutritious character, and accordingly half an hour after the operation, I introduced the stomach tube of elastic gum, and then passed into the subject's half a pint of wine and water. It was passed, without inconvenience, several times a day for the first week, and brandy, coffee, chocolate, soup, and other fluids then introduced, until the eighth day, when he could swallow with ease, without using having already taken place, from the quiet state in which the parts had been kept. I approved the use of the stomach-tube, in these cases, will remove much of the labour attending them, and be found greatly to promote the rapid recovery of the patients.—(See note on article *Osteo-Myeloma*—Rogers.)

JOINTS, DISEASES OF. The joints are subject to numerous diseases, which are more or less dangerous, according to their particular nature. Like all other parts, the joints are liable to inflammation and abscess; their capsules frequently become distended with an aqueous secretion, and the disease termed *Hydrops articuli* is produced; but the most important of all their morbid affections are the ones which a few years since were indiscriminately called *gout* and *ar-*

right, symphysis joints, and the distance of the hip-joint, those, as Mr. Brodie remarks, the same cause has been frequently applied to different diseases, and the same disease has received different appellations. And confusion with respect to the diagnosis always gives rise to a corresponding confusion with respect to the employment of remedies. Although, says he, diseases in their advanced stages extend to all the distal parts of which the joints are composed, still, it is not the case in the beginning. Thus, as elsewhere, the morbid action commences, sometimes in one and sometimes in another ligament, affecting in their nature, and, of course, requiring to be differently treated, according to the mechanical organization and vital properties of the part in which they originate.—(See *Pathological and Surgical Observations on the Joints*, p. 2, New-Land, 1816.) It was this idea, which led Mr. Brodie to trace by dissection the canal paths in which several of the principal diseases of the joints commenced, and here, with light and discrimination, his successful investigations have produced, it is needless for me here to insist upon, as his merit will long be acknowledged by every surgeon, who reflects the perplexity and ignorance which prevailed only a few years ago in this very interesting branch of surgery.

Wounds.—By the wound of a joint, surgeons mean a case where the capsular ligament is penetrated, or divided. The injury is often accompanied with a division of the ligament at other ligaments, and sometimes also with that of the cartilages and bones. That the capsular ligament is wound it may generally be inferred by the introduction of a probe, and frequently by a discharge of a transparent viscid fluid, called the synovia. But as a serous discharge may proceed from some wound of the bony surface, we might then be as erroneously judged, as we are unconquered with the situation of these fine tendinous bags. I am, at this present hour (Aug. 1822), attending a patient, whose leg was situated in a very serious laceration of a superficial laceration of the skin of the knee by a fall. A small abscess formed below the patella; and, very soon it burst, a considerable quantity of fluid, resembling white of egg, and evidently secreted by the neighbouring bursa, has been daily discharged without pain. Brodie has seen several cases, in which a fluid, resembling synovia, was discharged from wounds of the sheath of tendons.—(See *Virchow's Medical Observations*, 2. 4, p. 482.) Here the injury which I have given in another place (see *Remarks on the Abscesses*), reducing the severity of being too efficacious with the probe is equally important, inasmuch as the rough introduction of this instrument into a large joint, like the knee, would be likely to excite inflammation of the synovial membrane, and a train of dangerous and even fatal consequences, while the information gained by such employment of the probe is of little use; because whenever it is used is supposed to reach into the capsular ligament, exactly the same treatment should be followed, as if the joint were positively known to be penetrated.

Nevertheless simple wounds, even of large joints, often heal favorably, without any bad symptoms, this is not constantly the case, and the records of surgery furnish every example in which the most interesting and fatal consequences ensued.—(See *Wheeler's Commentaries*, part 3, p. 53.) When properly treated, painful wounds of the joints (says Brodie) are not in general attended with danger; but, in some of these wounds, which were apparently quite simple, have been followed by very bad symptoms, and even death, we should always be extremely on our guard in the prognosis.—(See *Virchow's Medical Observations*, 2. 4, p. 486.) The treatment consists in endeavoring to heal the injury by the first intention; or applying cold and sea-bath; and, in some of the parts; and employing bleeding and other antiphlogistic remedies.

Brodie observes two cases of fractured osseous of the knee joint, which healed up in a few days, without any extraordinary symptoms. He acknowledges, however, that these accidents are not always so untrifling, and that their consequences are sometimes serious.

Should indeed wounds prove very serious, particularly, viz. that of wounding the part by the first intention. At the moment of the accident, some of the synovia is discharged, indicating that the capsular ligament is wounded. Should this discharge not have been noticed at first, the surgeon may see the synovia flow

out again, if he move or press upon the joint. But, in making this examination, the greatest care must be used, not the irritation of the tendons ligament be increased. When the wound is large, and there is no considerable thickness of soft parts, the particular wound may extend to view.

The prognosis of an injured wound of a joint is not generally unfavorable, when the slices have been immediately brought together, the cavity of the joint not been long exposed, and blood is not effused into it. This last danger is also dangerous, as it is not noticed in speaking of collections of blood in joints. With these exceptions, says Brodie, the wound may heal as readily as if the joint were not opened; and he has cited several facts in proof of this statement. In such a case confirmed by the success which similar operations produced for the purpose of extracting extraneous substances from the knee. Nay, very bad cases sometimes recover under judicious treatment, even though the joint be large, and somewhat torn. Thus I saw, in St. Bartholomew's Hospital, in May 1821, two examples of compound fractures of the patella, where the capsule is the capsule was so thick, that the finger could hardly pass over the surface of the joint, yet, after large abscesses, a great deal of bone, and separation of bone, the patients recovered with stiff joints. But I would advise surgeons to be very cautious in this kind of procedure. Brodie is the most recent of patients treated of the large joints, when, in the circumstances already mentioned, the dislocation and gunshot wounds, are the same. In a case of a fall, the capsule of the knee joint was torn by the first intention. The rest of the longest consists in using every possible means for the prevention of inflammation, by perfect rest of the part, the use of cold applications, &c.

Let it be remembered, however, that wounds of the joints do not always heal in the above favorable manner. Even among these cases which appear the most slight and simple, there are but too many which are followed by more aggravated symptoms, as effusion of synovia or effusion of a necessary secretion. In other instances, if a too gross description, when the patient is cured, the termination of danger is not without an embolism, by which the motion and functions of the joint are permanently destroyed.

The experienced Mr. Brodie has noticed wounds of the joints, and made some pertinent remarks on the subject. He states, that, in these cases, no more care should be taken to prevent inflammation. "Upon this observation chiefly depends a successful termination. I have seen many cases, many large wounds of the great joints healed without the expectation of any dangerous symptoms, where danger has been taken to prevent inflammation; while, again, apparently trifling, well often be followed by a train of distressing and dangerous consequences, when such care has been neglected. It is generally easier to prevent inflammation in the joint after it is wound, than to cure it, progress when once begun. I speak now of inflammation affecting the capsular ligament. A slight degree of redness and tenderness in this neighborhood is of little consequence; but when the capillary system becomes inflamed, the formation of abscesses, attended with a high degree of fever, and ultimately a stiffness of the joint, are the common consequences, if the effort of the patient is prevented."—(See *Practical Observations on Surgery*, p. 254, edit. 2.)

For facts in confirmation of the foregoing Account, I particularly refer to several cases printed in the two publications, p. 255, 256, &c., and by Brodie.—*Treatise on Med. Chir.* (p. 425, &c.)

When the large joints, particularly the knee, are wounded, the stomach is frequently very much affected. Formerly, says, under the care of Mr. Bond of Newbury, a sick man, in the occupation of a brick maker, happened to give himself a wound, by which one side of the knee was laid open, a great deal of constitutional disturbance and of debility, and suppuration ensued; but what particularly struck me was the manner in which the stomach was so affected.

In speaking of dangerous substances in the joint, I shall have occasion to advert again to the danger of treating on wounded joints, and the same fact is still further considered in the articles *Dislocations*, *Fractures*, and *Gunshot Wounds*, &c.

which last part of the Dictionary the weakness of bones, ligaments, and other tissues to military surgery, are laid before the reader.

Inflammation of joints. If an episode from consideration specific cases, may be said usually to be the consequence of a contusion, sprain, wound or some other kind of injury; but with respect to the inflammation of the synovial membrane, as described by Mr. Brodie, an cause is so frequent as the application of cold, and almost to exclude the frequency of this disease in the knee, and its rarity in the hip and shoulder, which are covered by a thick mass of flesh. As a late writer observes, the inflammation arising from a wound is distinctly the same event after it, but was unattended—(*Lancet on Inflammation*, p. 157.)

The inflamed joint shews the common symptoms of inflammation: viz. puterential pain, increased heat, throbbing pain, and swelling, while the constitution is also disturbed by the common symptoms of inflammatory fever. It deserves notice, however, that as these upon the constitutional symptoms are often exceedingly acute, and the pain is some frequent, and sometimes full and strong, than when parts corresponded to nature in a state of health are affected. The inflammation first attacks some part of the capsular ligament, and very quickly spreads over its whole extent, as usually happens in all inflammations of smooth serous membranes.

The capsule of the joints is generally not very sensitive; but like every other part, similarly circumstanced, they often become acutely painful when inflamed. The membrane is accompanied with an increased secretion of the synovia, which becomes of a more aqueous, and of a less albuminous quality, than it is in the healthy state. Hence, it is now well estimated for increasing the articular stiffness, and preventing the effects of motion, as it is in the structural condition of the joint; a circumstance which may explain why a gelling sensation is often perceived on moving the parts.

The capsular ligaments, like other parts, are frequently thickened by inflammation, and sometimes completely tough being effused on their internal surface, organized cartilaginous or osseous bodies are formed within the joints.

It has been explained by Mr. Brodie, that the usual consequences of inflammation of the synovial membrane, or capsular ligament, are: 1. a puterential secretion of synovia; 2. an effusion of coagulable lymph into the cavity of the joint; 3. a thickening of the synovial membrane, a decrease of its folds a substance resembling gristle, and an effusion of coagulable lymph, and probably of serum, from the cellular structure, by which it is connected with the external parts. The three professions has seen several cases where, from the appearance of the joint and the symptoms, there was every reason to believe that the inflammation had produced thickening of the reflected folds of the membrane; in such cases: and, in dissection, he has occasionally observed adhesions which might have arisen from inflammation at some former period. "The effects of inflammation of the synovial very much resemble those of inflammation of the serous membranes. There are, however, some points of difference. In the former, I have reason to believe that separation rarely takes place independently of dissection; but this is a frequent occurrence in the latter. Inflammation of the peritoneum is pleura, though very slight in degree, and of very short duration, terminates in the effusion of coagulable lymph, but this is seldom the case in inflammation which has its seat in the serous membrane of joints."—(*Med. Clin. Phil.* vol. 4, p. 183.)

When the inflammation attains a high pitch, an abscess very soon in the cellular apparatus, which is latent beneath, and the pus makes its way beneath the skin, and is either in this discharged through abscessed openings.

An abscess rarely takes place in an important articulation, in consequence of mild inflammation, but when the process being more advanced than the itself is invariably endangered. Some severe symptoms always attend the process, and are usually followed by suppuration taking place, death itself ensues. Two steady fatal cases of abscesses of the synovial membrane, whose matter had formed within a few days of the hip, and a suppuration of the shoulder, are recorded by Mr. Brodie.—(*See Pathol. Clin. Phil.* p. 184.)

In these cases, the inflammatory fever is very quickly converted into the hectic, which, when an abscess has taken place in a large joint, is consequence of suppuration, hectic symptoms being immediately brought to view themselves, and the absorption of the contents of the inflammatory fever suddenly ceases.

Local consequences, even when these above described, may follow inflammation of a joint. As the liver of the ligament ligament reflected over the cartilages of the articulation is often inflamed, the cartilages themselves may have the inflammation communicated to them. Parts of a cartilaginous structure, being very incapable of bearing the influence of disease, often abscess, or, in other words, are absorbed, so as to leave a part of the whole of the articular surface of the bones completely denuded of its surface covering. At length the ends of the bones themselves become inflamed and become carious; or the consequence may be ankylosis. Mr. Brodie has seen some cases in which there was extensive destruction of the cartilages, apparently in consequence of neglected inflammation of the synovial membrane, but he believes that, in most cases where absorption of the cartilage is combined with such inflammation, the former is the primary affection, and the latter takes place subsequently, in consequence of the formation of an abscess within the joint.—(*Pathol. and Surg. Phil.* vol. 4, p. 17.) According to Mr. Brodie, he speaks chiefly of the inflammation which begins in the synovial membrane itself, and is not communicated to it from other sources, the disease very seldom attacks young children, but is frequent in adult persons, the nature of what happens in some other diseases of the joints.

The inflammation of the capsular ligament, in synovial membranes, frequently assumes the chronic form, and in this very often combined with other more serious suppuration, under the general appellation of white swelling. The disease often arises from cold, and hence is more common in the knee and ankle than in the hip or shoulder. It may also arise from the introduction of air or mercury, and, in particular, constitutions, from rheumatism, and general morbidly of the system. In these instances, it often leaves one joint not attacked another; and it is less severe, and less disposed to produce effects of coagulable lymph, in a thickened state of the membrane, than when it is accompanied by a local disease.—(*Brodie*, in *Med. Clin. Phil.* vol. 4, p. 183.) In the latter case, the disease is more likely to assume a severe character, and may be of long duration, leaving the joint with its functions more or less impaired, and occasionally terminating in its total destruction. The following are the chief symptoms of the complaint, pointed out by Mr. Brodie. At first, although sometimes a full over the whole joint, the patient feels a pain only in one spot, and it is not at its height before the end of a week or ten days. Sometimes, even at this period, the pain is trifling, but sometimes it is considerable, and every motion of the joint is distressing. In a day or two after the commencement of the pain, the joint is affected with swelling, which at first arises solely from a collection of fluid in its cavity, and in the superficial joints an effusion may be distinguished. However, after the inflammation has prevailed some time, the fluid is rendered less perceptible, either in consequence of the synovial membrane being thickened, or the effusion of lymph; and the more solid the swelling is the more is the bulkiness of the joint increased. The form of the distended joint does not correspond to that of the heads of the bones; but as the swelling is chiefly caused by the distension of the synovial membrane, it is lighter depends in a great measure on the amount of the synovial and fluid, which render it is certain distension, and allow it to take place in others. Thus, when the knee is affected, the swelling is principally observable on the anterior and lower part of the thigh, where there is only a yielding cellular structure between the osseous masses and the bone. It is also often considerable in the spaces between the ligaments of the patella and the lateral ligaments, because at these points the fluid accumulates is impeded completely by the collection of fluid. In the elbow, the swelling appears principally about the olecranon, under the extensor muscles of the forearm; and in the ankle, it is between the lateral ligaments and the tendons in front of the joint. In the hip and shoulder, where the distension is less frequent, the fluid tends to fill, but the

swelling is perceptible through the muscles. In the beginning of the disease in the hip, a fissure both in the joint and in the skin may be remarked; but afterwards the pain becomes flaccid, and the patient would soon want of rest. The pain is usually confined to the hip, but Mr. Brodie has seen cases in which it was also referred to the knee. It may be distinguished from the case in which the cartilages of the hip are affected, by observing, that the pain is more severe in the beginning than in the advanced stage of the disease; it never ascends to the extracapsular articulation, but in the other disease; and it is aggravated by motion, but not by pressing the cartilages against each other. The tracing of the pain is also preceded by a fulness of the veins. After the inflammation has subsided, the fluid is absorbed, and the joint frequently regains its natural figure and mobility; but in the majority of cases, stiffness and swelling remain, and the patient continues very liable to relapse, the pain returning, and the swelling being increased, whenever the patient exposes himself to cold, or exercises the joint a good deal. In cases where the synovial membrane is the lesion, a slow kind of inflammation continues in the joint, notwithstanding the fluid has been absorbed, and the principal swelling has subsided; the disease of length extending to the tendons, ligaments, and muscles, and the articular surfaces being completely destroyed. According to Mr. Brodie, at the advanced stage, the history of the disease, and not its present appearance, is chiefly to be relied on to determine whether the primary affection was inflammation of the synovial membrane, or of the cartilages. Though such is the most common situation of inflammation of the synovial membrane, it is admitted, that its nature is sometimes more acute, exhibiting the symptoms mentioned at the beginning of this section.—(*See Part II. and Surg. Obs. p. 21, 6c.*) He remarked by Mr. Wilson, that, when synovial inflammation is the cause, the white of it does not always adhere to the inflamed surface, but some of it does follow, which fluid in the fluid within the joint, is more liable to be absorbed, but through its capillary ligament. In other instances, the lymph becomes solid, adheres to the inside of the synovial membrane, and becomes permanent. The variety of new structures coming in successive growths, but occasionally a firm thick protecting mass, of different degrees of thickness and length, and as numerous as is desired every part of the original smooth surface of the synovial membrane, an exception is a preparation in Wundt's Museum.—(*See the Plates and Diagrams of Bones and Joints, p. 219.*)

When inflammation of the synovial membrane has arisen from a sprain, or all combined causes of injury, Mr. Brodie recommends a trial of sanguification; and when the disease is connected with rheumatism, the medicines adapted to combat this disposition, preparations of carbonate of ammonia, and other mild remedies for rheumatic eruptions. In some instances, however, in which several joints were affected, this preparation has known benefit follow from moderate doses of mercury.—(*Id. p. 31.*) But whether the disease be local, or dependent on the state of the constitution, Mr. Brodie considers topical remedies of great importance.

It will considerably shorten what we have to say concerning the treatment of inflamed joints, to observe, that, in the acute form of inflammation (the synovial membrane, the arthritic place, &c.) the full force of the expression is to be strictly adopted. But as there is a variety of cases often admitted to the same purpose, it seems necessary to offer a few remarks on those which lay the greatest claim to our consideration.

There are not many surgical cases in which power and especially topical bleeding is more strongly indicated. The violence of the inflammation, and the strength, age, and state of the power, must determine with regard to the use of the lancet; but the application of leeches may be said to be universally proper. When the leeches fall off, the bleeding is to be renewed by drawing the gum. The patient should rest in his bed, and until the acute stage of the inflammation has subsided. As Mr. Brodie observes, attention should also be paid to the state of the bowels, and saline draughts and diuretic medicines to be followed.—(*Part II. and Surg. Obs. p. 32.*) In connection with this treatment, the following practice may be employed.

In a few instances, however, the patient seems to derive more ease and benefit from the employment of compressions and emollient positions, which, according to Mr. Brodie, is the case when the swelling has been produced rapidly, and is attended with remarkable tenderness. But on this point, as I have mentioned is speaking of inflammation, the feelings of the patient should always be consulted; for, if the pain is materially alleviated by this or that application, the employment will hardly ever be wrong.

Nothing seems need be said concerning the use of the treatment proper during the violence of the inflammation, as the duty of the surgeon is not uniformly different from what it is in other cases where signs of importance are indicated.

As soon as the violence of inflammation has subsided, the great object is to remove its effects. Therefore a flaccid state of the capsule, ligament and parts surrounding the articulation, a stiffness of the joint, and pain, when it is moved; fluid in the capsule, &c.

At first, as Mr. Brodie has observed, the joint should be kept perfectly quiet, and blood should be removed from the joint, by means of leeches and cupping. The latter is the method in which the preceding writer gives the preference. The use of cupping is reported by Mr. Brodie to be continued until the inflammation has been abated, when a blister may be applied, and kept open with the same issue, as a preventive of future relapse, as performed by Mr. Brodie. "The blisters the day, though of considerable size; and if the fluid be depressed, they may be repeated as soon as it is possible; but otherwise with little success. Thus, when the synovial membrane of the hip is affected, they may be placed on the groin and thigh; but when that of the wrist is inflamed, they should be applied on the convex part of the forearm." Mr. Brodie thinks blisters have more effect than any other means in removing the swelling, but, extending to very light cases, for very highly constant this are supported by the observations of Boerhaave. After the subsidence of the inflammation, moderate exercise of the joint and stimulating liniments are recommended. The chapter on this is not completed, with the addition of leeches, cauteries, or thermal lotions, or the following formula, adopted as that in which the above principles seem to give the preference. R. Oculi vitæ 5ss. coll. sulph. 3ss. M. In this stage of the disease, I had the practice of holding compresses considerably dry, particularly when loaded with the weak liniment in the proportion of 1j. to 3j. Mr. Eschscholtz agrees for the use of Oculi vitæ to the leeches, and his words represent it as being rapidly absorbed from the surface of the skin, and acting very powerfully in dissipating the thickening and induration of various ligaments and sinews of the joints. Indeed, he orders such application of leeches in its several eruptions, and states that its effects are produced without the use of friction, so that it admits of being employed with advantage even when inflammation is present.—(*Essay on a New Mode of Treatment of Inflamed Joints, by Lind, 1802.*) Mr. Brodie speaks favorably of the effects of the antimonial ointment, in the proportion of 1j. of the vitæ, and 3j. of the antimonial. The use of good mercurial liniments as constant means in preventing relapses. Issues and sinews are very accessible, as the operation of the cartilages has light. For the removal of the remains of the swelling and stiffness, Mr. Brodie joins other writers in preferring the efficacy of blister and cauteries. The disease may be aided with compressed mercurial ointment with powdered starch; but the friction is to be moderate with caution, as otherwise it may produce a state of the inflammation. When this happens, it is to be discontinued, and blood taken from the joint. Mr. Brodie, who Mr. Brodie appears to consider highly liable to relapse to cases where the disease remains upon the state of the inflamed parts, than to cases where it arises from disease in the joint itself. With regard to the plan of allowing a course of warm water to fall on the part, as suggested by Dr. Brou, and followed in the watering places, he allows that it is beneficial, but that it requires the same caution as the employment of friction.—(*Part II. and Surg. Obs. p. 33, 4c.*)

Before and with several instances in which I have composed of single and moderate amounts of leeches, and for the removal of the chronic inflammation, after the acute stage of the disease. The practice of

swelling of joints are also valuable applications; and they may be extended upon other instances, which will thus be rendered more efficient.

The serosity of the constitutional symptoms is mostly, if not always, greater when the inflammation of a large joint arises from a wound, than when it is the consequence of a lesion of vessels.

Large Cartilages in Joints.—Hard, rounded, or flattened bodies, chiefly of a cartilaginous nature, are sometimes formed within the capsular ligament, occupying some or less parts in the affected joint, and a considerable impediment to the freedom of their movements. The disorder, though not noticed by any of the very ancient writers, is not from being common. Pank is the first who speaks of it; he says, that a hard, polished, white body, of the size of an almond, was disengaged from the knee of a patient, in the year 1520, in which he had made an incision for an abscess upon the patella, about a hydropic antrum. (Linn. 25, chap. 1, p. 272.) A banded, and three times three afterwards, viz. in 1611, Pechin published the full details of another case, in which a cartilaginous body was successfully extracted from the knee. (Ullmann, *Physica Med.* vol. 26, p. 376.) Dr. A. Mead, in 1720, described the knee-joint of a woman, who had been blind, and found in the articulation a cartilaginous body, of the shape and size of a small bone. These were the only examples of the disease known before the year 1740, at which period Mr. Stagnut cut out of the knee a staphylo substance, which he supposed of the size of the operation was only beneath the skin. (Stagnut, *Med. Essays*, vol. 1.) But of late years the disease has been frequently noticed and described, successively by Bonard, Boer, Mikulic, Goussier, First, House, Bell, Abernethy, and Berd, in England; by Bonard, Thiers, and Laffay, in Germany; and by Bonard, and Salomon, in France. Hence, as before remarked, it is now so well known, to most others, to whom the joints are subject.—*Trans. du Med. Chir.* 4, p. 424.

Such bodies do not resemble cartilages, are not peculiar to the knee, as they occur in other joints; yet they are most frequently met with in the knee, and it is in this joint that they produce symptoms which render them the object of a surgical operation. Morgagni and B. Bell met with them in the ankle. Haller in the joint of the jaw, and they in the elbow.

According to Mr. Richard Brown, these substances are anomalous in their structure to bone; but in their external appearance they have a greater resemblance to cartilage. They are not, however, always exactly of the same structure, being in some instances softer than in others. Their external surface is smooth and polished, and being lubricated by the synovia, allows them to be moved readily from one part of the joint to another. They seldom remain long at rest while the joint is in motion; and when they happen to be in situations where they are pressed upon, with force by the different parts of the joint, they occasion considerable pain, and extremely interfere with its necessary actions.

The resemblance of their being loose, and having no visible structure, made it difficult to offer good conjectures respecting their formation; and according to Mr. E. Brown, so extensive a number of their origin had been given when Mr. Hunter made his observations. In the course of his experiments, instituted with the view of proving a living principle of the blood, Mr. Hunter was naturally induced to attend to the phenomena which took place when that fluid was extravasated, whether in consequence of accidental violence or other causes. The first change he found to be coagulation; and he supposed thus formed, it is covered with living parts, and we presume are identical, similar to tubercles, cancer, &c. was it dissolved and taken back into the circulation, but in many instances proceeded in living power, and would occasion an erysipelatous inflammation from the neighbouring blood vessels in the adjacent parts; it afterwards underwent changes, rendering it similar to the parts to which it was attached, and which supplied it with nutriment. When suppuration added to a surface which owed its position, the affected part was rendered in some instances puscular, and in others it was merely broken.

Hence it was easy to explain the manner in which these gelatinous bodies are formed, which are sometimes attached to the sides of the synovial cavity,

and the principle being established, it became equally easy for Mr. Hunter to apply it under other circumstances, that it is evident from a known law in the animal economy, that extravasated blood, when first dissolved as separated part of the body, and before the nature of the parts into which it is effused, and consequently the many coagulum which is thereby effected might form a soft tubercle, would, when situated on a bone or in the neighbourhood of bone, afterwards be a hard one. The cartilages found in the knee joint, therefore, appeared to him to originate from a deposit of coagulated blood upon the end of one of the bones, which had acquired the nature of cartilage and had afterwards been separated. This opinion was further confirmed by the examination of joints which had been violently strained, or otherwise injured, where the patients had died at different periods after the accident. In some of these cases there were small gelatinous parts, particularly found, as he had to examine, and to distinguish to be chiefly knocked off by any sudden or violent motion of the joint.—(Trans. for the Improvement of Med. and Chir. Knowledge, vol. 1.)

Mr. Brodie met with three cases, however, in which the loose bodies were of a different nature, and had a different origin from that referred to by Mr. E. Brown. Sometimes he met with a bony nodule in the knee, like a small cartilage, seated the margin of the cartilaginous surface of the joint. In the two examples related by him, the tubercle grew of bone and taken place, and, in consequence of the motion of the parts, portions of it had been broken off and lay loose in the cavity of the joint.—(Litt. and Chir. Trans. vol. 4, p. 278.) And in a more recent publication by Berwick, that in the majority of cases which he has met with, no inflammation preceded the formation of these gelatinous substances, and therefore he thinks it probable that, in some instances, they are produced like other tumours by some different process. He further observes, that they appear to be seated originally either on the internal surface, or in the substance of the synovial membrane, where, before they become detached, a thin layer of the latter may be traced over them.—(Pathological and Surgical Ess. p. 294.)

One or more of these gelatinous bodies may be formed in the same joint. So E. Brown mentions one instance in which there were three; they are sometimes about the size of a horse bean, often much smaller, and sometimes considerably larger; when very large, they do not give so much trouble to the patient as the smaller kind. A soldier of the 5th regiment had one nearly as big as the potato, which occasioned little uneasiness, being too large to disengage itself from the lower parts of the joint. Morgagni saw many of these in the left knee of an old woman, who died of apoplexy, and Haller met with no less than twenty, in the articulation of the lower jaw. When there are several in the same joint, it is observed, that their size is generally small.—(Esper, *Trans. du Med. Chir.* 4, p. 426.)

The diagnosis of this disease, as Brown observes, is seldom attended with any difficulty. When the formation of the extraneous substance follows a fall or blow upon the joint, the complaint begins with a swelling of the surrounding soft parts, and upon the subsidence of this swelling, which lasts for a few days or less, both the presence of the false cartilaginous tumours is indicated by certain symptoms which are peculiar to them. In persons who have had no blow but fall upon the knee, the disease sometimes commences with a more or less acute pain in the joint, with or without swelling of the surrounding soft parts, and which afterwards is usually regarded as rheumatism. To these first symptoms, which are common both to cases of foreign bodies in the joints, and other diseases of these parts, are some additional particular signs, by which the nature of the case is evinced.

As the extraneous bodies are in general free and movable in the joint, they can easily be made to slip about from one part of the articulation to another; a circumstance which is facilitated by the motion of their surface, as well as by the synovia, which is usually in larger quantity than natural. According to the situation which they happen to occupy, sometimes they produce some pain, sometimes no pain whatever. When they lodge in a depressed hollow they are not compressed, they cause no pain; and if they could be always kept in this position, their presence would not

say the entire loss of the motion of the knee. An example in which the patient died after the operation, in St. Bartholomew's Hospital, was the first in the collection of many others.

As the disorder is often attended with a degree of heat and tenderness in the articulation; as the danger of the operation is, in a great measure, proportioned to the subsequent inflammation; and as proof of the danger is at once removed if the incision made by the first incision, the advice to keep the patient in bed a few days before operating, to apply leeches and cold antiseptic lotions to the knee during the same time, and to exhibit beforehand a saline purgative, is highly prudent.

I shall next introduce an account of the plan of operating, as described by several of the best modern surgeons.

As these knee joints cannot always be found, no time can be found for the operation; but the patient, who will soon become familiar with his own complaint, must learn to bear with a favorable situation, and retain them there till the surgeon can see him.

"Before the operation, the knee should be extended upon a table in a horizontal position, and secured by means of assistants; the knee cartilages are to be pushed into the upper part of the joint above the patella, and then to one side; the lower side is to be protected, so that situated only the rotator internus would only be divided in the operation. Should there be several of these bodies, they must be all extended, as the operation should be postponed till some more favorable opportunity, since the leaving of one will subject the patient to the repetition of an operation not only painful but attended with some degree of danger.

"The knee joints are to be secured in the situation above mentioned by an assistant, a task not easily performed while they are cut upon, from their being loosened by the operation; and if allowed to escape into the general cavity, they may not readily, if at all, be brought back into the same situation.

"The operation consists in making an incision upon the loose capsule, which it will be best made in the situation of the thigh, as the incision will more readily be healed by the first incision. If the skin is drawn to one side gradually by making the incision, the wound through the parts underneath will not be accompanied with that pain in the skin, which circumstance will favour their union. The incision upon the capsule must be made with caution, as it will with difficulty be retained in its situation if much force is applied. The assistant is to endeavour to push the loose body through the opening, which must be made sufficiently large for that purpose; but as this cannot always be done, the incision if at any point may be passed while ago as to lift it out, or a sharp pointed instrument may be struck into it, which will fix it in its situation, and bring it more within the advantage of the operation.

"The cartilages being all extracted, the cut edges of the wound are to be brought together, and, by means of a compress of lint, not only pressed close to one another, but also in this plane underneath, in which situation they are to be secured by sticking plaster, and the rotator ligaments.

"As soon as the last incision is of the utmost consequence, this operation, to prevent an inflammation of the joint, the patient should remain in bed with the leg extended, till the wound is perfectly healed, or at least all chance of inflammation is at an end." (*Howe in Trans. for the Improvement of Med. and Chir. Knowledge, vol. 1, p. 221, &c.*)

In the instance, though proceeded in the following manner: the surgeon, after extending the capsule ligament by extending the leg, brought the extraneous body on the inside of the articulation against the attachment of the capsule ligament, and secured it in this situation between the tibiae fuge and oleum of the left hand, while an assistant drew the ligaments forwards towards the joint. The joint covering this extraneous body was not divided by any incision one inch in length, and its extraction accomplished by pushing it from above downwards, and raising it anteriorly with the end of the knife. This instrument, in extension, was fixed similar to a corner to the cartilages that cover the articular surface: it was three quarters of an inch in length, six lines and a half in

width, and three lines in thickness; its surface were smooth, one extremity the other convex; its distal extremity triangular, diversified with red points, forming small depressions; the middle was rounded, the outside of a cartilaginous texture. As soon as the substance was extracted, the assistant let go the instrument, which he had drawn forward; they immediately returned to their natural situation on the inner side of the knee joint, in such manner that the extraneous moved in the articulation was extracted upwards from the one to the capsule ligament. Two advantages were prepared by this means; on the one hand, air was prevented from penetrating into the articulation, and on the other, the flexing portion of capsule ligament, retained in place by the skin, was more likely to attach itself to the condyle, in case it did not unite to the other portion of the capsule already more reattached. The edges of the wound were brought into contact by means of the sewing machine; dry lint and compresses were applied, and pressure on the part by a tight bandage; and the limb was kept in a state of extension. (*Osborne's Journal, t. 2.*) According to Mr. Abernethy, the inner surface of the internal capsule of the os femoris presents an excavation, and is really a pitted surface, which terminates in a fringed at its upper part by a cartilaginous layer a portion of a circle. If the point of the knife be firmly pressed upon this edge so as to form a kind of line of circumscription, several thin cartilaginous bodies, they cannot pass into the joint in this direction, even if they made away with on account of the loose state of the internal articulation. Hence these substances are after the surface, which may be directly felt; and they may be exposed by simply dividing the integuments, ligament, and the capsule of the joint.

In an interesting case which Mr. Abernethy relates, the incision of the knee was greatly pressed towards the internal condyle, and the ligament of an assistant applied round the circular edge of the bone. The incisions were greatly divided towards the knee fronting, and lengthened until divided transversely over the knee substance, to the extent of an inch and a half. This withdrawing of the integuments from the natural situation was designed to prevent a direct correspondence of the external wound to that in the capsule of the joint; for when the integuments were suffered to return their natural position, the wound in them was nearer to the joint than the wound in the capsule. The flaps which covered the joint having been exposed by the division of the integuments, it was divided in a similar direction, and nearly to the same extent. The capsule is now laid bare, and gently divided to the extent of half an inch, when it covered one of the loose substances which suddenly slipped through the opening, and by pressing gently upon the flaps it was also discharged. The bodies thus removed were about three quarters of an inch in length, and half as wide in breadth. They had a highly polished surface, and were fixed like cartilage. The fluid contained in the joint was pressed towards the wound, and about two ounces of synovia were discharged. The wound of the integuments was then gently drawn towards the opening and accurately closed with sticking plaster. (*Medical Observations, 1804.*)

When there are several extraneous cartilaginous bodies in the joint operated upon, the surgeon must be careful to extract them all through the same wound, if it can be done without producing too much irritation of the capsule ligament, and they will admit of it. But frequently only one can be made to prevent itself at a time, or this be easily extracted. Each of the bodies will then require a separate operation, which is a disadvantage than disturbing the plan by one and repeated attempts to extract them all at once. (*Wegler, Trans. for Med. Chir. t. 2, p. 445.*) The surgeon is also often obliged to make his incision at a particular point, because also they can the extraneous substance be fixed. A case confirming all these facts observations was lately published by Dr. Clarke. (*Ann. Med. Chir. Trans. vol. 5, p. 87.*) In this instance the operation was three performed upon the same knee joint with perfect success. Mr. Brooke also executed five knee cartilages, by three different operations, without any subsequent synovial effusions, although the patient appears to have been previously subject to repeated attacks of synovial inflammation of the joint. (*Philos. Magaz. and Berg. Obs. p. 259.*)

On the preceding subject, some observations and two admirable appendices have been lately published by James Barry—*On the Ankyrosis of the Joints*, 2, 2, p. 421, &c. With the exception of a few wrong notions, his appendices have given a fair account of the disease.

Hydrops articuli signifies a collection of serous fluid in the capsular ligament of a joint. The knee is more subject than other joints to serous effusion, which has been known, however, to affect the wrist, ankle, and shoulder joints.—(Barry, *Treatise on the Joint*, &c. 4, p. 436.)

Mr. Barry adds the opinion that water comes of this kind from the vessels supplying the joint, but the opinion does not rest on any foundation. Hydrops articuli is not really coming from exudation, inflammation, effusion, or even fluid, the presence of excessive cartilaginous bodies in the joint, and is produced in any way which irritates the capsular ligament; such, as already explained, it is a common effect of inflammation of the synovial membrane; the capsular effluvia sometimes diffuse fibres; but in most instances it is purely a local affection, quite independent of general debility.—(Barry, 4, p. 437.)

Hydrops articuli presents itself in the joint of a soft member, determined by the distension of the capsule; increased, without change of colour in the skin; accompanied with a fluctuation; it is violent, and very little painful; causing hardly any impediment to the motion of the joint, yielding to the pressure of the finger, but not resisting any depression, as in aneurism. The swelling does not occupy equally every side of the joint, being most conspicuous where the capsular ligament is loose and superficial. In the wrist it occurs at the anterior and posterior parts of the joint, but especially in the former situation, which is more perceptible at the sides. In the ankle it is more apparent in front of the malleoli than any where else; and in the shoulder it does not surround the joint, but is almost always confined to the front of it, and can only be seen in the depression between the distal and great pectoral muscles.

In the knee joint, which is the common situation of hydrops articuli, the tumour does not occur behind the articulation; but at the front and sides. Behind, the capsular ligament is too much in the way of being much distended with the synovia; while in front and beside it is relaxed, so that it can then yield considerably in proportion to the quantity of fluid increase. The swelling is at first circumscribed by the thickening of the capsular ligament; but in consequence of the accumulation of fluid, it is uniform and extends to the thigh bone and the external malleolus of the leg, which are lifted up by it. By its tension it yields to the upper third of the thigh. The swelling is irregular in shape; it is most prominent where the capsular ligament is wide and loose, and it is in some measure divided longitudinally into two lateral portions, by the patella, the ligament of the patella, and the point of the external malleolus of the leg; all which parts the synovia rises, and pushes forwards, though in a much less degree than the capsular ligament. In these lateral portions, the internal is broader and more prominent, because the part of the capsule between the patella and edge of the internal condyle being higher than that situated between the patella and edge of the external condyle, yields in a greater degree to the distending fluid. The motion of the leg, which are generally little interrupted by this disease, make a difference in the shape and consistency of the swelling. In flexion, the tumour becomes larger, looser and weaker, and more prominent at the sides of the knee-joint, which is supported, depressed by its ligaments. In extension, the tumour is softer, and the distension smaller.

In order to feel directly the fluctuation, which is one of the best symptoms of the disease, the ends of two or three fingers should be placed on one side of the swelling, while the opposite side is to be struck with the end of the middle finger of the other hand.

The patella being pushed forwards, away from the articulation, is very movable, and, as it were, floating. When it is pushed backwards, while the leg is extended, it can be set on to a certain way. Before it meets with the resistance of the articulation, it is set on to the pressure being discontinued, it immediately separates from this part again.

By such symptoms, hydrops articuli may easily be distinguished from other diseases of the joint, from aneurism of the same system under the same symptoms of the leg; from ganglion in front of the knee-joint; from rheumatism, &c. &c.

The prognosis is most favourable when the swelling is recent and small, and has been quick in its progress like the tumour, when the tumour is of long standing and large, the effused fluid thick and firm, and the external vessels thickened, the removal of the fluid by absorption, and the restoration of the part to their natural state, will be both slow and difficult. The worst case is that which is connected with disease of the capsular ligament, cartilages, and bones.

The cure of the above-described species of affection of the joints depends upon the absorption of the effused fluid. And when the cure is considered with acute or chronic inflammation of the synovial membrane, the treatment is the same, as that already recommended for those particular cases of disease. When inflammation exists, the absorption of the fluid is sometimes altogether prevented, and it must always be promoted by friction, by rubbing the joint with clove-plaster, mercurial ointment, the use of a blister of cantharides, the very blister (intending it) of the nature of a cure. In every 100 gr. of it, and particularly by the employment of blisters.

The operation of a blister may be advantageously instead with a moderately sized blister. When after it has been made of size, two more blisters should be made, each incorporated with the first of about, electricity, and the addition of mercurial ointment. When hydrops articuli occurs chiefly to destroy the support to the joint and other forces, the operation is hardly to be expected to get well before the patient requires more degrees of strength.

As, however, hydrops articuli is generally quite a local disease, Barry contends that it should be chiefly treated with topical remedies; and he has given emulsion, salivary, hydropic, &c. as emulsion is efficient.—(Barry, vol. 4, p. 437.) He is strongly in favour of repeated blisters, both for the prevention and cure of the disease.

Craniotomies do not often justify the swelling of an opening into the joint; but excessive extension in more neglected cases, might certainly be an agreeable remedy for such an operation. Also, if the complaint should resist all other plans of treatment, and the retention of the tumour greatly impairs the strength, then, the operation would be justifiable. An interesting example of this kind is related by Mr. Latta.—(History of Surgery, vol. 2, p. 439.)

It is best to make the opening in such a way that the wound in the capsular ligament after the operation will not remain directly opposite the wound in the skin. For this purpose, the incisions are to be pushed to one side, before the incision is made.—(Encyclopædia Medico-chirurgica, vol. 4, p. 439.)

The operation is not always successful, being sometimes followed by alarming symptoms, which arise slowly and faintly, or occasion a necessity for amputation. The fluid also generally collects again, and in the synovial membrane is mostly thickened, it often diffuses, and suppuration in the joint ensues. Lastly, when hydrops articuli originates from rheumatism; when it is recent, sudden, and not large; and when it does not seriously impair the function of the joint, Barry recommends the operation, not to be done. But he maintains its performance when the disease is long, longed with excessive cartilaginous matter in the joint, or when it is very considerable, and attended with severe pain and impairment of the function of the joint.—(Op. cit. 4, p. 437.)

Collection of Blood in Joints.—More symptoms writers speak of this kind of case, though it is not uncommon. They speak of the joints, composed of blood, and set down in numerous English books as a variety of cases with the synovial ligaments, are possibly in the hands of the joint.

When blood happens to be extruded off and if a large articulation, however, no more would be gained, involving an opening for its escape. As the symptoms are likely to result from its more presence, and the absorption will, as the rest, take it away. If an incision were made into the joint, the coagulated matter

of the extravasated blood would suggest such blood to be easily discharged.

The first plan is to apply absorbent restraints; loines of flannel, spirits of wine, and masses of ammonia for the first three or four days; and afterwards, friction with camphorated liniments may be easily adopted.

Mr. Hey states a case in which the knee-joint was swollen, and blood extravasated itself into the synovial ligament; yet, though the effusion could not be ligatured, as it was emitted from the extravasation, which was absorbed without having created the synovial inflammation. (*Practical Obs. in Surgery*, p. 236.)

White Swelling.—The white swelling, or synovitis, as it is now of late often more correctly called, in inflammation of the Articular membrane, Ligaments and Articular, has been a disease indiscriminately applied to many diseases, which differ widely in their nature, causality, and treatment. Wharson was the first who used the term white swelling; and if the synovitis and the associated ligamentous inflammations of every different kind, and each kind could be found with it, because it signified every concept as one of the mark of some of these diseases, which is, not notwithstanding the increase of size in the joint, the pain is generally not inflamed, but retained its natural colour. (*Part. 1*.)

The name therefore appears objectionable only inasmuch as it has tended to suppress the introduction of a sufficient number of well founded and necessary distinctions. Synovitis, however, has previously been connected with a distinction into two kinds, viz. the chronic and acute.

The first species of the disease they also distinguished into such varieties, as primarily affect the bones, and then the ligaments and articular parts, and into various cases in which the cartilages, ligaments, and soft parts become diseased, because there is any marked affection of the bones.

Mr. Brodie has endeavored to form a more correct classification of the different complaints to which the joint white swelling is applied; and his description is so valuable, because obtained by extensive observation and accurate dissection. With respect to the disease beginning in the ligaments, if the capsular ligaments be put out of consideration, it is, in this gentleman's view, a rare occurrence, and he has never met with a case in which the fact was proved by dissection. (*Practical and Surgical Obs.* p. 7.)

1. The first case is inflammation of the synovial membrane, as described in the foregoing pages, especially that form of the disease which often arises from cold, and resembles the disease formerly often termed a rheumatic white swelling.

2. Another form of disease, not exactly comprised under the general name of white swelling, has been particularly described by Mr. Brodie: the disease originates in the synovial membrane, which loses its natural organization, and becomes covered over a thick, pale substance, of a light brown, and sometimes of a reddish brown colour, arising by white membraneous lines, and first, $\frac{1}{2}$ of an inch, or even more than six or eight in thickness. As this disease advances, it involves all the parts of which the joint is composed, producing inflammation of the cartilages, surface of the bones, and of the ligaments, and sometimes in different places. The complaint has frequently proved slow in its progress, and sometimes has remained nearly in an indolent state for many months, or even for six or ten years; but says Mr. Brodie, "I have seen, and written instances in which a red inflammation was produced, such has been known to be in which a case was effected." (*Obs. Medico-Chir. Trans.* vol. 8, p. 335, &c.) The joint in nearly the whole of the synovial membrane has always been found inflamed; though if a very early examination were made, Mr. Brodie conceives that this might not be the case; and in one example he found only a half of the membrane thus altered, while the rest was of its natural structure. (*Practical and Surg. Obs.* p. 34.) This gentleman further observes, that the preceding affection of the synovial membrane is rarely met with except in the knee; that he has never known an instance of it in the hip or shoulder; that it is peculiar to the synovial membrane of the joint; that he has never known an instance of it in any other soft part, nor even in the synovial membrane, which constitutes the knee capsule and sheath of tendons; and that it generally takes place in young persons.

above the age of puberty. In fact, Mr. Brodie has not met with more than one instance in which it occurred after the middle period of life. Mr. Hodgson, of Birmingham, it seems, has met with one example of it in the ankle; and another in one of the joints of the fingers. "In the origin of this disease, there is a slight degree of stiffness and transpiration, without pain, and producing only the most trifling inconvenience." These symptoms gradually increase; at last, the joint acquires a degree of the synovial action, the stiffness being greater than when it is the consequence of simple inflammation. The form of the swelling bears some resemblance to that in cases of inflammation of the synovial membrane, but it is less regular. The swelling is soft and elastic, and gives to the hand a sensation as if it contained fluid. Highly one would be employed in making this distinction, the absorption may be complete, and the more experienced surgeon may be led to suppose there is fluid in the joint when there is none; but, if both joints be employed one on each side, the absence of fluid is distinguished by the want of fluctuation.

The greatest experience tells us no pain until afterwards begin to form, and the swelling increases and then the pain begins to become so when the inflammation of the cartilages occurs as a primary disease, and the disease had more gradually, and undergoes a greater quantity of pain than in cases of the last description. At this period, the patient becomes affected with hectic fever, loses his flesh, and gradually sinks, unless the fluid be removed by an operation." (*Med. Chir. Trans.* vol. 5, p. 251, 252.) In the tragedy of cases, Mr. Brodie believes, that the gradual progress of the enlargement, the stiffness of the joint, without pain, and the soft elastic swelling without fluctuation, will enable the practitioner readily to distinguish this from all other diseases of the joint. However, when the disease spreads, inflammation happens to be accompanied with a quantity of fluid within and takes of considerable length, the complaint somewhat resembles in its feel and appearance that stage of gonorrhoea in the bladder of the synovial membrane, where the part is not thickened, and more or less distended with considerable fluid; but the possibility of removing the former case by the same means which cure the latter, and the agreement to the history of the disease, will prove the difference between them. (*Practical, Pathol. and Surg. Obs.* p. 36.)

3. Observation of the articular cartilages takes place in the advanced stage of several diseases of the joint, and it also takes in many instances a primary affection, in the early stage of which the bones, synovial membrane, and ligaments are in a natural state. If neglected, it ultimately occasions the entire destruction of the articulation. It may be the consequence of inflammation of the cartilage itself, or of the bony surface with which it is connected; but, as Mr. Brodie further observes, in many instances there are no evident marks of the disorder being preceded by any inflammatory action in one part or the other, and the inflammation, which afterwards takes place, appears rather to be the greatest spot, than the cause of the absorptive process. One striking peculiarity of observation of the articular cartilages is, that there occurs very little pain when the joint is in a state of pain. For the disease often proceeds so far as to cause entire loss of the bone, and yet no painful matter is found within the joint. (*Practical, and Surgical Obs.* p. 317, &c.) The investigations of the same author dispose him to believe, that a conversion of these cartilages into a soft spongy substance is a frequent though not constant consequence of absorption. (*P.* 321.) When the absorption of the cartilages shows in the superficial part, it constitutes one of the diseases which have been known by the name of white swelling. From cases which Mr. Brodie has met with, he is led to conclude, that when it takes place in the hip, it is the disease which has been variously denominated by writers, the "swelling near the hip," the "displacement of the hip," the "swelling of the hip," the "displacement of the hip," &c. At last, says Mr. Brodie, in this disease, that these names have been principally applied, though probably they implied affections that have occasionally been attended with it. (*Med. Chir. Trans.* vol. 8, p. 236.) The absorption of the articular cartilages takes place, as a primary disease, chiefly in children, or adults under the middle age. Of every eight persons of

affected with this disease, fifteen (according to Mr. Brodie) years under thirty years of age; the youngest was an infant of about twelve months; the oldest was a woman of sixty. As the knee is more frequently affected by inflammation of the synovial membrane, so the hip-joint is more liable than other joints to the invasion of the cartilaginous surface. In general the disease is confined to a single joint, but it is not very unusual in two or three joints affected in the same individual, either at the same time, or in succession. Sometimes the patient incurs the laceration of his synovium to a local injury, or to his flexor being employed in a violent way, for the most part, no cause can be assigned for the complaint."—(*Med. Chir. Trans.*, vol. 6, p. 219).

The symptoms of the disease of the hip-joint will be described in the ensuing section, and we shall here content our remarks to the synovial characterizing inflammation of the cartilages of the knee, as pointed out by Mr. Brodie. They differ from those of inflammation of the synovial membrane, by the pain being slight in the beginning, and gradually increasing very intense, which is the reverse of what happens in the latter affection. The pain in the osseous part is also unattended with any evident swelling, which seems to be less than that of two weeks, and often not illusive several months. It is very uncommon, however, that every slight pain of the joint, unaccompanied with swelling, want of motion, from laceration of the cartilages. But, says Mr. Brodie, when the pain continues to increase, and at last is very severe; when it is aggravated by the motion of the bone as in some other, and often, after a time, a slight increase of the joint takes place, we may conclude that the disease exists in both directions. The swelling arises from a slight inflammation of the cellular membrane on the outside of the joint; it has the form of the articulating ends of the bones; and for the most part it appears greater than it really is, in consequence of the vessels being wasted. No fluctuation is perceptible, as when the synovial membrane is inflamed; and is then the peculiar elasticity which exists when the synovial membrane has undergone a marked alteration of its structure.

Mr. Brodie has explained, however, that in some cases the swelling has a different shape, and even resembles the foot of a flatulentus. The progress when inflammation of the synovial membrane, attended with a collection of the synovia of the joint, or abscess in the surrounding soft parts, or in the articulation itself, were as secondary diseases. When there has been considerable destruction of the soft parts from abscess and ulceration, the head of the tibia may become detached and driven towards the knee.—(*Med. Chir. Trans.*, vol. 6, p. 225, &c.) In the first vol. of this work, Mr. Mayo has described an acute form of ulceration of the cartilages, as displayed in three cases affecting the knee, elbow, and ankle. They were all attended with severe pain in the beginning; two ended in absorption, after antiseptic treatment for two months; and the third patient, a boy, died, during the influence of this disease, of an injury of the head. The bones of the ankle-joint were found almost stripped of cartilage; what remained of this tissue was softened, and that accordingly but it seemed in other respects unchanged, and subjected firmly to the bone.

A third person's illustration of the synovial membrane, which Mr. Brodie considers in a separate section, and now proceed to the description of the swelling. In the synovial disease of the joints, the most commonly affected, is consequence of violent ulceration takes place in the cartilages covering their articulating surfaces. The membrane being ulcerated, the subsequent progress of the disease (says Mr. Brodie) is the same as when this ulceration takes place in the first instance.—(*Med. Chir. Trans.*, vol. 4, p. 265.)

By Mr. Lloyd, sometimes with swelling are displayed into three stages, the first being that in which the affection is confined to the bone; the second, that in which the cartilaginous parts become detached and wasted; and the third being that in which the osseous stage, attended with ulceration of the cartilages, inflammation of the synovial membrane, and abscess.—(*the Novels*, p. 111.) It was formerly a common notion, that in white swellings the heads of the bones were swelled enlarged. Mr. Keil, I believe,

is the first writer who expressed an opposite sentiment, and he distinctly declares, that he has never heard or known of an instance, in which the tibia was enlarged from an attack of white swelling.—(*P. 27*.) The tenacity of the opinion was somewhat pointed out by Mr. Lawrence, in the late Mr. Crookes, and the subject was mentioned in the best edition of the "First Lines of the Principles of Surgery."

Deceived by the fact of white thinned joint, and influenced by general opinion, I once supposed that there was possibly a regular expansion of the head of scrofulous bones. But, excepting an occasional enlargement, which arises from absorption of bony matter, deposited in the cavity of the tibia, tibia, and, which otherwise cannot be called an expansion of these bones; for a long time, I never met with the head of a bone enlarged, in consequence of the disease known by the name of white swelling. I was, however, much in the habit of inspecting the state of the numerous diseased joints which were every year presented at St. Bartholomew's Hospital, and though I was long attentive to this point, my attention was not really enlarged scrofulous bone always passed in review. Not more than at that period any instance of an expanded head of a scrofulous bone in Mr. Keil's museum. Within the last few years, however, a specimen of an enlargement of the upper end of the tibia has been found, and it was some time ago shown to me by Mr. Stanley. Mr. Langens is said to have in his possession a knee-joint, in which the bone and tibia are said to be expanded. The natural size of the bone not being thicker than when the tibia is of its natural size, and the vessels being, though of regular greater solidity than natural.—(*Lloyd's Novels*, p. 111.) However, that the head of the bone is enlarged does not resemble the common scrofulous affection of the heads of the bones. I say not, that Mr. Wilson, whose dissections were very numerous, contains with the best modern writers respecting the state of an osseous expansion of the extremity of the heads of the bones.—(*the Novels*, p. 111.) I have also heard of a few other instances, in which the heads of the bones were actually enlarged in cases of white swelling. However, I believe the enlargement is far from being usual, and doubts may yet be entertained whether such enlargement is connected with the osseous affection of the bone. The change which the head of the tibia undergoes in many cases is first a partial absorption of the phalange of bone throughout its surface, while at first a consequent fluid, and afterwards a yellow cheesy substance, are deposited in the cavity. In a more advanced stage, and, indeed, in that stage which most frequently takes place before a joint is amputated, the head of the bone has long since become in consequence of cancer, and its structure is more or less altered, and when an instrument is pushed against the osseous part, it easily penetrates deeply into the bone. Occasionally, as Mr. Lloyd has observed, at the base of a joint are affected in this way, but frequently only one of them.—(*the Novels*, p. 111.)

According to a modern writer, "The osseous affection appears to interfere with the bone, which becomes progressively vascular, and contains a large vessel quantity of earthy matter, which is not a consequence of that, and afterwards a yellow cheesy substance is deposited in their cavities. From the osseous bone, vessels carrying and blood, and into the cavity, which often and becomes a cyst, the cavity then beginning on that surface which is connected to the bone. As the nature of the bone of process, is destroyed in the joint. At last the osseous bone, finally, having become absorbed and dissolved."—(*the Novels*, p. 111.)

—(*the Novels*, p. 111.) The above description of the structure of the bone, this author has observed in the osseous, within the cavity of the osseous bone, it is asserted by persons who write that the osseous matter sometimes permeates the cavity of the osseous bone, and is deposited in the osseous process of the most minute size.—(*the Novels*, p. 111.) Also, with respect to the osseous matter of the diseased part of the bone, which Mr. Lloyd asserts to be the truth of this statement, as applied in the early stage of the disease, he expresses the osseous matter as afterwards being dissolved, in proportion to the quantity of osseous matter deposited in the cavity.—(*the Novels*, p. 111, 112.)

A cursory examination of a diseased joint, even when it is hot to the touch, will not suffice to show that the bones of the lower have not acquired an increased size. In making a description of this kind, in the presence of a medical friend, I found that even after the joint had been opened, the swelling had every appearance of arising from an actual expansion of the bones. The gentleman with me felt the ends of the bones after the dissection had been removed, and he coincided with me that the feet which was even very much increased seemed to be caused by a swelling of the lower three inches. But on closing them, the enlargement was demonstrated to arise entirely from a thickening of the soft parts. As known, indeed, is the experience of the hands of the lower, than the late Mr. Croxall, who paid great attention to these cases, joined Mr. Russell in believing that such a change never happened; a conclusion not entirely correct.—(*See Practical Gen. on White Swelling*, 4th ed. 2, p. 14, 1805.)

Mr. Russell has particularly noticed how much the soft parts frequently contribute to the swelling. He describes the appearance on dissection thus: "The great cause of the swelling appears to arise from an effusion of the joint exterior to the cavity of the joint, and much less from an enlargement in size, even able to have undergone a material change in structure. There is a layer than natural proportion of blood fluid intermixed with the gelatinous substance; and the delicate ligamentous stuff has become thicker, softer, and of less firm consistency, than is a state of health."—(*On the Medical Affections of the Knee*, p. 30.) The manner in which the soft parts are affected is also described by Mr. Brooke. "Inflammatory action plays in the cellular membrane external to the joint. Swollen, and somewhat congested, lymph, etc. effused; and hence, arises a puff elastic swelling in the early, and an enlargement resulting in the advanced, stage of the disease."

Scrofula attacks only those bones or portions of bones which take a spongy texture, in the extremities of the extremities, and the bones of the carpus and tarsus; and among the joints becomes affected from their contiguity to the joint which has the original seat of the disease.—(*See Medical Clipp. Yr. 1816*, vol. 4, p. 273.)

In the cavity of the joint we sometimes find a quantity of white like matter, and the cartilages absorbed in chronic places, but more particularly round the edges of the articular surfaces.

As the course of the disease implies, the skin is not at all altered in colour. According to Mr. Lloyd, the first decided symptom of disease is the stimulating fatty matter of a knee, is an occasional disordered, dull, heavy pain, unattended by swelling, and not increased by motion; and if it be the hip, knee, or ankle which is affected, the patient keeps the knee rather bent, and never fully extends it in progression.—(*On Scrofula*, p. 128.) In some instances the swelling yields to a certain degree to pressure; but it never goes, and is almost always sufficiently firm to make an undisturbed extension believe that the bones can bear the weight. It is remarked by Mr. Brooke, that while the disease is going on in the spongy structure of the bones, by far the efforts have extended to the other tissues, and while there is still no evident swelling, the patient experiences some degree of pain, which, however, is never very severe, and often it is so slight that it is scarcely noticed. After a time, varying from a few weeks to several months, the external parts begin to swell, and soon and augmented though, to be effused in the cellular membrane, so as to form a puff, elastic swelling.—(*Practical Obs.*, p. 211.) Is the quantity of scrofulous white swelling, let the skin be dried or moist, never it is perfectly transparent in one part of the joint; viz. after the course of the articulation or the head of the shaft. Sometimes the joint continues without interruption; sometimes there are attacks, and it is more tedious, the pain returns at regular times, as far as have been called by some writers periodical. Almost all authors describe the patient as suffering more or less in the advanced part, when he is warm, and particularly when he is in the exercise of his bed.

In the early stage of the disease the swelling is usually very considerable, or there is even a visible enlargement in motion, arising perhaps after exercise. In the little depressions, naturally situated on

each side of the patella, a fulness generally first shows itself, and gradually spreads all over the affected joint. According to Mr. Lloyd, however, when the soft parts on the outside of the knee-joint permanently swell, the swelling of the cartilages of the knee-joint, just behind the condyles, so that the joint appears wider; and he says, that he has often seen the swelling first commence by the swelling of a gland immediately above the inner condyle. He observes, however, that there is no point of the joint where the swelling may not begin.—(*Op.*, vol. 4, p. 128.)

The patient, unable to bear the weight of his body on the diseased joint, is consequently of the great tendency of pain then created, goes into the habit of only touching the ground with his toes, and the knee being generally kept a little bent in this manner, soon loses the capacity of being completely extended again. When white swellings have lasted a good while, the knee is almost always found in a permanent state of flexion. In scrofulous cases, the pain constantly presents any appearance of abating; but the interval between the two symptoms differs very much in different subjects.

The patient, as the disease of time, requires a violent treatment. But the interstices retain their natural colour, and remain unaffected. The enlargement, however, always seems greater than it really is, in consequence of the position of the limb both above and below the disease.

An appearance of blue distended veins, and a shining synovial, are the only alterations to be noticed in the skin covering the enlarged joint. The shining synovial seems attributable to the distention, which authorizes the external firmness and weakness of the tissue. When the joint is thus rendered the integuments cannot be pushed up, into a fold, as they could, in the state of health, and even in the beginning of the disease.

As the progress of the articulation advances, the cartilages become, and collections of matter form around the part, and at length burst. Their progress, as Mr. Brooke has stated, is slow, and when they burst, or are opened, they discharge a thin pus, with portions of a mud-like substance, floating in it. The discharge afforded becomes less copious and thicker.—(*Practical Obs.*, p. 224.) The advanced openings sometimes heal up; but such abscesses are generally followed by other collections, which pursue the same course.

In some cases, these abscesses burst a few months after the first affluence of the joint; on other occasions, several years elapse, and no appearance of this kind makes its appearance. They sometimes communicate with the cavity of the diseased joint, or lead down to diseased bone, portions of which occasionally exfoliate. In the greater part of cases, several abscesses take place in succession, some healing up, and others making its return.

As the cartilage continues to absorb, Mr. Brooke has observed, that the pain becomes aggravated, though not to a very great degree, and he says that it is not severe until an abscess has formed, and the parts over it are distended and inflamed.—(*Practical Obs.*, p. 224.)

The local mischief most commonly produces more or less constitutional disturbance. The patient's health becomes gradually impaired, he loses his appetite and natural heat and energy; his pulse is small and frequent; an obscure debilitating diathesis and profuse, morbidly even sweat. These complaints are, at first, followed by disordered, and the constitution is relaxed in time, either by the weakness or removal of the diseased part. In different patients, however, the course of the disease, and its effects upon the system, vary considerably, in relation to the rapidity with which they occur.

Extensive white swellings, or inflammation and thickening of the synovial membrane, from cold or other causes, are very distinct diseases from the scrofulous distension of the large joints. In the first, the pain is still severe to some without being attended with swelling. Scrofulous white swellings, on the other hand, are always preceded by a pain, which is particularly confined to one point of the articulation. In chronic cases, the pain is more general, and diffused over the whole joint.

Mr. Lloyd thinks, that the scrofulous white swellings may be distinguished from all other diseases of the joints, by its being attended with less pain, by its

point degree of internal swelling, often existing for a long time before manifesting in the cavity of the articulation, and by the swelling being but little diminished by any discharge of matter, which may take place. In the first stage, before the interior of the joint is affected, it may be distinguished from ordinary inflammation of the cartilages by the pain not being greatly increased by motion. The pain is increased by stretching the joint is also extensively less in this disease than in ordinary inflammation of the cartilages.—(*Read's Medical Observations*, p. 132.) And according to Mr. Brodie, the principal distinction between synovial disease of joints and the primary affection of cartilages, is the little degree of pain in the former case, which is never nearly so great as before an abscess forms, nor particularly severe, "except in a few instances, and in the most advanced stage of the disease, when a portion of abscessed bone has died, and having exfoliated, so as to be loose in the cavity of the joint, irritating the parts with which it is in contact, and thus becoming a source of constant trouble."—(*Read's Medical Observations*, p. 136.)

It seems probable, that cases in which the cancellated structure of the bone is found quite undisturbed; and in which the union of disease is confined to the soft parts, are not sufficient to give swellings. Few persons who have attained the age of five and twenty, without having had the least symptom of scrofula, ever experience after this period of life, a first attack of the white swelling of the synovial fluid. The general coherence of this observation, I believe, is universally admitted, and that there are but few exceptions to it is confirmed by the statements of Wilson, of Paris. However, Mr. Lloyd attended a man, who, at the age of between forty and fifty, died of phthisis, and had at the time a scrofulous tubercle, hidden beneath abscesses about his hip and groin. And the same practitioner met with another patient upwards of forty years of age, with a scrofulous disease.—(*De Scrofula*, p. 127.) But if these patients had had no mark of scrofula in their younger days, a scrofulous ear, specified, they then deviated from what is normal, as indeed Mr. Lloyd seems to admit. My own observations tend to concur with Mr. Brodie, that the scrofulous affection of the joints is frequent in children, are rare after the age of thirty.—(*Read's Medical Observations*, p. 136.) This observation, however, is to be received as correct, only with reference to persons who have been free from scrofula up to that period of life. I am attending at this moment (Aug. 1828), a woman who is nearly forty, and was first attacked with a scrofulous white swelling of the left knee about a year ago; but there she had enlarged glands in the neck in her youth, and a scrofulous ulcer of long duration laid open on one of her legs. All cases in which the internal structure of the heads of the bones become softened, particularly in the articulation of the cartilages and soft parts, are probably scrofulous.

Mr. Brodie has noticed the frequent enlargement of the lymphatic vessels in the joints in consequence of the latency of the disease in the bone; but he justly adds, that the secondary affection never prevents the resolution.

When the bones are diseased, the head of the shaft always suffers more than the remainder of the shaft.—(*Read's*) The outer surface of the femur sometimes has not a single rough or carious point, notwithstanding that it is diseased; this may have suffered a great deal. The cartilaginous coverings of the heads of the bones are generally eroded first at their edges; and in the bone, the cartilage of the tibia is always more affected than that covering the condyles of the femur-bone. Indeed, when white swellings have their origin in the bone, and the bone is the seat of the disorder, there is some ground for supposing that it is the thin part of the articular surface of usually first compromised.

The ligaments of the knee are occasionally so weakened or destroyed, that the tibia and fibula become more or less dislocated backwards, and drawn towards the tibial end of the femur, by the powerful action of the flexor muscles of the leg. It is observed by Mr. Brodie, and just as descriptive of the condition is sometimes followed by dislocation of the hip, to see first the dislocation of the knee occasionally take place from the other cause. When there has been considerable distension of the soft parts, in conse-

quence of attention attending to them, the head of the tibia is gradually drawn backwards by the action of the flexor muscles. And Mr. Brodie observes how this happens, previously to the formation of any abscess.—(*Read's Medical Observations*, p. 172, &c.)

I have seen a curious species of white swelling, in which the leg would be torn to pieces by a very moderate violence, both when the knee was resting and when it was in motion, a state implying a permanent laceration, or perhaps a destruction of the ligaments of the articulation.

Sometimes white swellings, as Brodie has said, are confined to a particular kind of resolution, some scrofulous or strumous kind, in which every case capable of exciting inflammation, or any morbid and variable state of a large joint, may bring on the most severe disease. On the other hand, in a more or a second condition, a similar irritation would only induce a transient, limited inflammation of the joint. In scrofulous cases, it also seems as if irritation of a joint were much more easily produced than in other constitutions: and as one can doubt that when once excited in the former state of subjects, it is much more dangerous and difficult of removal, than in other patients.

The decline of particular white swellings being scrofulous disease, is supported by many weighty reasons, the evidence of the most accurate observers, and the evidence of daily experience. Wilson (l. c. chap. 8.) calls the white swelling a species of scrofula, and adds that before and during its progress the subjects of this disease. The disorder is said by Boerhaave to be exceedingly frequent in young subjects. Petrus de Marchetti has observed both male and female subjects affected with what are called strumous diseases of the joints, as early as the age of five and twenty; but not ascertained, among them, had suffered from scrofula before that period of life, and had not been completely cured. If, however, the disease takes a similar origin. Even though a few years have elapsed since the onset of the joint, for the first time, after the age of twenty-five, this occurrence, by the first attack of scrofula after this period, may be considered as sufficiently confirmed.

Another argument in favor of the disease which sets down strumous kinds of white swellings as scrofulous, is founded on the hereditary nature of such forms of disease.

Numerous continental surgeons, particularly Hall and Wankel, have noticed how seldom the tibia and femur are both scrofulous and white swellings of the joint. We every day see that young persons affected with the present disease, are in general scrofulous constitution, or have once been so. Properly examined synovial glands in the neck denote the first possibility of scrofulous; and very often the patient are known to have diseased feet, persons who had numerous tumors.—(*Cranch's*) The disease is generally connected with enlarged lymphatic glands, or abscessed bones.—(*Read's Medical Observations*, p. 131.) All the authors observe, since the disease depends upon a scrofulous condition of the system, it is not surprising that we should sometimes find it affecting several joints at the same time, or that it should attack itself in different joints in succession, attacking a second joint after it has been cured in the first, or after the first has been relieved by amputation.—(*Read's*, p. 131.)

Besides the general condition of a scrofulous constitution, which will be noticed by the reader, I suppose, we may add others as a striking exemplification. First, scrofulous, like white of egg, blended with the most subtle such diseases as occur in the progress of the disease. This kind of matter is almost peculiar to scrofulous abscesses, and forms another description of species of the foregoing observations, relative to the disease which scrofula frequently has in the origin and nature of many white swellings.

Mr. Brodie's experience leads him to believe, that in scrofulous cases, the chance of ultimate recovery is much less, when the disease attacks the articulation of the foot and hand, than when it is confined to large articulations of a more simple structure.—(*Read's*, and *Chap.*, p. 233.)

Treatment of White Swellings.—In practice we meet with these cases, both scrofulous and non-scrofulous, in two opposite modes, sometimes the disease

joint is affected with a degree of acute inflammation, whether transient or permanent, is entirely chronic.

The impudence of patients in walking about and limping the diseased part, is often the occasion of a degree of acute inflammation, which is denoted by the tenderness of the part when touched by the fingers, and also by the symptoms feeling denser than those of the chronic form. When such state exists, there can be no doubt that topical bleeding, fomentations, diathermia, &c., or cold sensitive issues, are means which may be extremely serviceable. The inflammatory reaction is now strongly indicated. Cooling purges of the same kind should also be exhibited. Blood may be taken from the arm, and sent from the diseased part, either by means of leeches or cupping. Mr. Latta gives the preference to the latter method, whenever it can be employed; and he very properly remarks, that this advantage can be expected from topical bleeding of any kind, unless the quality of blood taken away be considerable. Ten or twelve ounces by cupping should be taken away at a time, and the operation should be repeated at proper intervals till the tenderness and heat of the skin have entirely subsided. When leeches are used, the number ought to be considerable, and Mr. Latta recommends the application of at least sixteen or twenty.—(*System of Surgery*, vol. 1, p. 463, 4).

Although inflammatory means are judicious when acute inflammation prevails, yet such preparations as are warm and morbid in the opinion of the ancients are highly censurable. While the skin is hot and tender, while the joint is affected with very acute and general pain, and while the patient is infested with the inflammatory action of inflammation, great benefit may be rationally expected from the above plan. When, however, the disease is truly chronic, different plans are indicated. In ordinary cases of chronic disease of the joint, Mr. Brodie considers topical bleeding as generally unnecessary.—(*Practical and Surgical*, vol. 1, p. 466).

It is quite tedious to expatiate on the mode of treating white swellings accompanied with acute inflammation, particularly as the treatment of those cases, which consist of inflammation of the synovial membrane has been already noticed, and may be said to be applicable to other forms of white swelling, when they are attended with heat and inflammation of the soft parts. The most eligible plan of removing the morbid process is the leech, and the most successful method of lessening the disease, independent of the joint, are the various means of promoting the action of excretion.

The works of Hippocrates, Celsus, Aetius, Rhazes, Paracelsus, &c. charged with modern surgical books, will scarcely bear us, that the practice of the ancients, in the treatment of diseased joints, does not differ much from the plan now pursued by the best modern surgeons. Mr. Crookes remarks, that the ancient and modern practice, with bleeding and stimulating applications to the skin. They further ascertain, that even produced by these means should have their discharge promoted and continued to a considerable length of time.

With regard to the case which Mr. Brodie describes as depending upon a local loss of the natural moisture of the synovial membrane, which is converted into a fatty substance, one quarter or one half of an inch in thickness, though the progress of the disease may be somewhat checked by rest and cold lotions, it is according to this gentleman's remarks, and at length it comes to a crisis of the cartilage, abscess, &c. Why there is considerable pain in consequence of the cartilage beginning to decay, partly relief may be derived from sedatives and potasses; but nothing will effect a cure. When, when the joint begins to suffer, as considers absorption and suppuration.—(*Med. Clin. Trans.*, p. 254). Whether the use of effluvia applications could be beneficial in the early stage of this form of disease, is a question that deserves further investigation, but this only be determined by careful observation.

When white swellings are accompanied with chronic disease of the cartilage, all modes of the joint is extremely painful. Indeed, as Mr. Brodie well observes, feeling the limb is a state of perfect numbness, a very agreeable state the most exquisite sensibility,

to be appended to in the movement. According to this gentleman, it is in this disease, in which alteration of the cartilage occurs as a primary disease, that ankylosis is most readily produced of singular benefit; but he observes that of late time in any other disease of the joint. He thinks sedatives and warm, kept open with various means, may also be used with advantage. Bleeding is indicated only when there is frequent recurrence, the irregular motions are increased, and there is pain and fever. Mr. Brodie asserts that the worst kind of ankylosis is the early stage, if it does not stop the progress of the disease, but he considers patients of great dissipation, extravagance, intemperance, and intemperance, as either useless or harmful.—(*Med. Clin. Trans.*, vol. 1, p. 330-334).

Topical applications, consisting of strong solutions of the mineral and vegetable kingdom, are of no service in destruction of vibration of the cartilage, or of the synovial form of the disease, though they often suffice in the cure of some mild descriptions of white swelling, depending upon a thickening of the synovial membrane. A doctrine of our last, consisting of ankylosis, was promulgated by Mr. Russell.

My own experience will not allow me to say any thing in favour of electricity, as an application for the relief of white swelling; and it must be more likely to do harm than good, whenever the indication is to loosen the joint.

"If the tumour is quite indolent (says Richardson), the application of galvanism may be proposed; it is not, however, except from danger, and on our occasion when I employed it, stimulating pains and swelling of the joint were brought on by it."—(*Nervous*, Clin. 1, 3, p. 124, 2).

Mr. J. Brodie had experience in chronic white swelling as possessing power over every chronic disease, and that such diseases of the joint are often naturally benefited by the patient's going to the sea-side and bathing, is a fact which cannot be denied. Whatever may be the mode of explaining the benefit thus obtained, I fully believe that sea air and sea bathing have a beneficial influence over chronic diseases of the joint; but probably their effects are confined to the part through the medium of the constitution, and they should only be recommended as an auxiliary plan, to be adopted in conjunction with other well chosen medicinal treatment.

Every one is well acquainted with the efficacy of friction in exciting the action of the absorbents. To this principle we are to apply the great benefit which arises from what is termed dry rubbing, in cases of white swellings. This kind of friction is performed by the naked hands of an attendant, without any ankylosis than any kind of friction is either application whatsoever, ankylosis sometimes a little heat, or powdered starch, and the rubbing is continued seven or eight times a day. At first, many joint patients used to turn their head round by drawing themselves in this species of labour, in which they were paid a stipend of six pence per hour. This practice, however, is chiefly advantageous in the chronic stage of white swelling, aiding first inflammation of the synovial membrane.

I look upon all ankylosis as a disease, such as inflammation and suppuration, or acute disease of real efficacy, except when first pain or active inflammation is present, and, though they were in some cases, the patient, they ought not to be encouraged. Thus, except when, only, it is to be used to relieve the patient's fever, without doing any real good to him in regard to his affection, may be considered as doing harm, because the suppuration of swelling being done, the patient is under great trouble and pain from being moved. The French surgeons are particularly liberal in the joints which they remove on white swelling, ankylosis, suppuration, &c., and they consider instances of white swellings being cured in this manner. But the cases to which they refer were by no means ankylosis, and, according to the synovial swellings; a disease which is peculiarly ready to yield to other plans.

The only method of treatment which my own personal experience enables me to recommend for white swelling is a chronic state, requires in keeping up a discharge from the surface of the diseased joint. The operations which I have had of ankylosis the effects of having had chronic ankylosis, (this is not my intention, as given the same to the same).

(JUGUM TESTIS). A continuous large cavity the posterior end of an incision doubling the value in permeability as capable to retain the fluid in the bladder. A jagged, strongly speaking, jagged incision that operates by sucking up the part of the urethra. A jugum of the kind, which was illustrated by Nark, is described in Hirst's Surgery—(See tab. 30 fig. 8 & 9). And a large incision is likely to take place a jagged incision on this principle is not applicable, and indeed is necessary to create pain, and is not found to succeed. Donald's incision for rendering a stricture simple, noticed in the article CURE. Incontinence of a still lower age was proposed by Lee Hanks—Jones, de Vol. Clin. et Pharmacol. 1. 10 p. 101. Wherein even the left side is possible, and a permanent to be given. An apparatus for securing the urethra directly it escapes from the stricture, in the incision. A few minutes of such assistance may be found in Jurell's Treatise on Gynaecology. The instrument consists of three pieces; viz. 1. A very small, a small tube of elastic glass, and a silver flask is inserted into the place of the incision, a small hole, which gives rise to the water. The (very small) is made and about 10 days is sufficient. In an external edge there are several small holes, through which the liquid is passed, which causes it to be the best. The small surface is highly engraved, so that it may adjust itself perfectly to the particular shape. The small surface is rather convex, and formed with a continuous double perforation in several places, to which the elastic very neck or tube is fastened. The lower part must be four or five (seven, ten, and with enough to hold the penis, as desired, and is made to work on to the lower half. At the upper part of the opposite three pieces, which form each other is a straight arm, and serve for fixing a sponge with the urethra. The silver flask is four inches wide, and of a flat shape: is like on the inside of the neck, or in a pocket made in the branches. If necessary, a larger flask may be used. According to Mr. Mackenzie, of Glasgow, a Swedish kind of the penis in the stricture answers very well in stricture, some after laboratory.—(See fig.)

self-defense is now frequently attacked with vehemence and vigor, more than the club itself. According to Professor New York in the *Register*, N. Y. 343, this vigorous indignation of the laymen should be very rare, and he desires that, in the course of a practice of twenty years, he has very seldom met with one. On this point he differs

the tendency to contract the folds, out, and on, organic structure that instead of these folds, or that of performing the motions, as played by Woodhouse, it would be better to endeavor to restore the natural mode by removing the obstructions in the nasal duct, which obstructs Pott regarded as the cause of the disease. The method consisted in opening the lachrymal sac with a small trocar, introducing through the nostril, sac, and making a probe down into the duct, and then using bougies for the dilatation of the passage. This method may be said to be the model of that which has been most extensively followed, even down to the present time. Pott and Warton (before mentioned) the introduction of a spiral tube down the ducts directly, and leaving it for a time to this position, with a view of preventing the duct from closing again; and the use of a cannula becomes now preferred by Traquair, the greatest success of France.

The danger of leaving any substance of the sac has influenced many practitioners besides Aert, and given rise to various ingenious contrivances. Thus, in 1770, the William Elliot proposed, instead of inserting bougies to introduce squabbles through a small puncture, communicating with a long tube full of this fluid. The specific gravity of the squabbles when the eye was diseased with it, he supposed would force them down the lachrymal duct through any stricture, to remove the lachrymal obstruction.

The late Dr. Ware, attempting to restore Pott's plan, gave the substance of Aert's syringe, with which he generally injected warm water, through the same position, lachrymal into the lachrymal sac, and put a finger over the superior punctum to prevent the fluid from escaping through it. With his finger he also occasionally compressed the lachrymal sac, in order to assist in propelling the water down into the duct. The squabbles used this injection water a day, except in general warm baths frequently. — See *Ware on the Eye*, p. 41.

His general plan the treatment by injecting water warm every second the inferior punctum, lachrymal, and I repeat the injection about five days or sometimes, if, in this space of time, none of the water goes through the duct into the eye, and if the watering of the eye continues as troublesome as it was before the injection was employed, I usually use the angular vein, or draw a blood to be applied over the lachrymal sac: adding here a caution, that the blood be not pulled to it, or either of the eyelids, but to pass over an obstruction of blood in the angular vein. About the same time, that blood is taken away in the neighborhood of the eye, I usually rub the injection, and try the effects after a week, or, at the most, two weeks. In some instances, also, when I have found it impossible, after several attempts, to inject any part of the fluid through the duct, I have introduced a golden probe, about the size of a lachrymal, through the superior punctum lachrymal, and, according to the direction of the duct, have introduced its extremity through the choroid, and, conveyed it fully over the same, immediately after which I have found, that a fluid, injected through the inferior punctum, has passed without any difficulty — and by repeating these operations for a few successive days, I have at length established the freedom of the passage, and discharged the eye. In other instances, I have occasionally a success, immediately afterwards to be considered as the case, about a year before the time of the patient's death, which, as before, I effected a high discharge from the lachrymal punctum, but, when, there also, every method to open the duct has failed in the long run.

A Conjunctival Yarn, which may not be relieved by any of the means above related. — (Ware's *Observations on the Eye*, p. 41.)

When conjunctival yarn has been used, Mr. Ware sometimes found, that a serious injury happened to the eye, quickly corrected by means of the probe.

In a subsequent 1783, Dr. Ware observing, that if, after a short time, in ten days, there be not some perceptible advance towards a cure, or, if, after the long continuance of the obstruction, there be reason to fear that it is too firmly fixed to yield to this long mode of treatment, I do not hesitate to propose the operation which is now to be described. The only persons who should be subject to this operation are those who, in the frequency of this complaint are labored. In such persons I

always think, it advisable to propose the operation, unless the symptoms be particularly urgent, and they are either or very great.

If the disease has not terminated in a stricture in the lachrymal sac, or if this stricture be not situated in a right line with the longitudinal direction of the duct, it is possible about to make into the eye, at a great distance from the internal junction of the probe, and, seeing as with a wire, immediately from this junction towards the nose, with a very narrow open pointed lance. The first end of a silver probe, of a size rather smaller than the probe that we commonly used as a syringe, should then be introduced through the second, and gently, but steadily, be pushed on to the direction of the duct, with a force sufficient to overcome the resistance in the duct, and until there is reason to believe that it has freely entered into the cavity of the duct. The position of the probe, when first introduced, will be nearly perpendicular, and will limit the upper edge of the duct; and the space between its bulbous end in the eye, and the second in the duct, usually be small, in which the probe moves, as to about an inch and a quarter, or an inch and three quarters. The probe then to be withdrawn, and a silver style of a size, slightly smaller than that of the probe, but rather smaller, about an inch and three quarters in length, than the last, the end of a nail, left placed slightly, that it may not enter the eye, when it is introduced through the duct in a right line of the probe, and, to be left constantly in it. For the first day or two after, the eye has been introduced, it is sometimes advisable to rub the eye with a weak astringent lotion, in order to relieve any swelling or inflammation, which may have been excited by the operation; but this is general advice, and should have rarely been applied to use any application is required. The style should be withdrawn every day for about a week, and afterwards every second or third day. Some writers have recommended that the style be inserted through the duct into the eye, and the instrument be afterwards replaced in the same position as before. I strongly advise to move the end of the style with a piece of dry cotton, plaster spread on black silk, but without touching the necessity for applying any remedy by blackening the head of the style with wax or resin.

Mr. Ware did not, as first trying this method, expect any relief till the style was left off. However, he found, that the watering of the eye ceased, so long as the style was introduced, and the sight became proportionally more useful and strong.

The wound, which Mr. Ware made in the eye, when there is no regular stricture, appears, is only just large enough to admit the end of the probe or style; and has even become a healing ulcer, though when the style only is passed without the least pain or distress, is about a week or ten days, the wound becomes so dry, that the patient, or his friend, is fully competent to do what is necessary. It rarely occurs in withdrawing the style that at times there is a weak, occasionally increasing, more warm humor, and then re-joining the instrument as before.

Since, finding no inconvenience from the style, and being able to leave it off, over it, for years, some others advise it to stand a month or six weeks, are otherwise quite well. The operation sometimes failing over the lachrymal sac, commonly lead to no more use than the probe down into the eye; and Mr. Ware sometimes has instances, in which the style has been left a week or more of the lachrymal duct, and has been afterwards removed. — See *Ware on the Eye*, p. 41.

Next to the impossibility of the lachrymal probe, and, if, by Mr. Ware, Dr. Traquair is strongly disposed to think, in which, lachrymal probe has been used, and finding the style remains in the passage. When, at intervals over the eye has been closed, the difficulty indicated the introduction of a style like the ducts easily, immediately after the introduction of the duct with a lachrymal. — If the probe passes without meeting into the eye, the case requires no further operative treatment, the lachrymal probe, to healthy condition, and in the next application, the ducts gradually distributed, and the lachrymal duct. If, on the other hand, after communication with the probe, introduced through the wound into the eye, resistance is offered in its passage into the eye, no more favorable opportunity will be presented, for

great advantages would be gained by the use of this instrument: one, of exhibiting invariably the lateral incision of Chamberlain; the other, of constantly guiding the patient, through the whole course of the operation, from injury of the ureters, and of the urethra, from injury of the prostate. The utility of the latter object being frequently disputed, as it is evident that the necessity of the direction of the instrument depends on the extent of the injury, and that its cutting edge and being inclined to constantly traverse the ureters and sinuses of the bladder, and to follow upwards in the direction of the longitudinal axis of the neck of the urethra, cannot avoid the great injury. But with respect to the first advantage, or that of extending constantly the lateral incision of Chamberlain, it is to be admitted that it does not completely fulfil the intention which he proposed, not only on account of the cutting edge of his instrument not being placed exactly above the level of the sling, to penetrate sufficiently the substance of the prostate gland, and consequently to divide it to a proper depth; but likewise, being too much turned upwards of that point, so as to lay open the base of the prostate gland, it does not divide it liberally, but rather at its upper part, towards the summit of the ramus of the bladder, and the neck of the prostate, its opening of all others in the perineum the least complete, and presenting the greatest impediment to the passage of the urine from the bladder.—See also *Key to Lithotomy*, p. 183. The breadth of the point of the director is, besides, so disproportionate to the diameter of the membranous part of the urethra, that, from the great resistance with which it meets, the instrument may easily slip from the groove of the staff, and pass between the bladder and rectum, a serious accident, which has very often happened even in the hands of experienced surgeons.

Scarpa considered the modifications of Chamberlain's point proposed by R. Bell, Denon, Cline, and Crusk, as a depreciation of the original instrument. R. Bell (the observer) has distinguished the breadth of the director, but given the cutting edge a horizontal direction. The horizontal direction of the cutting edge is also preferred by Denon, Cline, and Crusk; but they have enlarged the director and transverse part which, from necessary reasons. Aware of the danger of widening the point entry by the horizontal direction of the point, they direct the handle of the staff to be inclined towards the patient's right groin, and the point to be pushed along it, instead of which a mistake that its oblique edge may be directed towards the rectum, and the cutting edge placed at a sufficient distance from the urethra, and hence of the patient to avoid wounding the artery. Scarpa considers, however, that it is difficult to direct a proper degree of obliquity to the staff, and that such limitation of the instrument must be hypothetical, arbitrary, and unstable, in comparison with that position of it in which the handle of the staff is held in a line parallel with the body of the patient, and is accurately placed against the arch of the pubis; on the instability of the instrument. (See Scarpa's) the safety and precision of the lateral operation depend. According to this opinion, and position, the defects of Chamberlain's original point arise from the excessive breadth of the director, consequently at the point the mere of sufficient elevation of the cutting edge above the level of the groove of the staff, and the inevitable inclination of the edge to the axis of the urethra and prostate gland. The review of the mistakes in a cross between thirty and forty years of the lateral operation, done in the hands of the apex of the prostate gland, first shows its tendency and how some of the failures of Chamberlain. The apex of the prostate gland is rather more than two lines in thickness, the body or middle part, and the base six and sometimes eight, which exceeds the radius of the bladder. In an adult of middle stature, from sixteen to twenty years of age, the thickness of the base of the prostate gland is about two lines less, increased but that of a man of forty, and of a large size. The prostate lies in which any patient previous of the prostate gland should be made in a white (very large), is found to be inclined to the longitudinal axis of the neck of the urethra, and of the gland itself, at an angle of 45°. From these facts, it is seen that the structure of the parts, Scarpa makes the direction of the point very thin, too small and too short; the breadth decreasing at the base. The cutting edge of the instrument is

straight even to point, but gradually rises, and becomes convex above the level of the staff, so that the point enters it to a considerable extent. Lastly, the inclination of the cutting edge to the longitudinal axis is not at right angles at all, but at 45°, and in some, the angle is the full angle of the prostate gland to the longitudinal axis of the neck of the urethra.—See Scarpa's *Almanac on Medicine's Gargel*, 1799, p. 12, 13.

For more than twenty years this instrument was used in London, has been in the habit of being a point which Mr. Abernethy invented, and which is in the peculiarity of its cutting edge turned up as an acute 60°, leaves much room in the instrument itself, as is pointed by Scarpa. The cutting edge is straight, and that incision and dangerous part of a proper, somewhat round the shoulder, is removed. Adverting to the principles of the lateral operation, as explained by Scarpa, we observe, and of which I shall presently speak, it appears to me that Mr. Abernethy's point is the preferable to that very recently proposed by Scarpa. Its edge is not an indefinitely turned up, but it is even with more care, and less risk of slipping from the staff, because it has not any projecting shoulder, which, while the staff is firmly held, holds the back of the point in it, and causes the other effect, by this abstracting the passage of the fluid instrument.

Grooves which cut on both sides have also been sometimes employed in England, and as a point having can be obtained by them, even without touching the base of the prostate gland by Scarpa, that is, without cutting any part of the body of the bladder, they appear to present utility, especially when of which is suspected to be large. However, they can be used now than they were, some years ago, when Dr. Andrew Cooper employed them in Guy's Hospital, and I am acquainted with the personal reasons of Scarpa.

In the United States, when the subject is said, that of Dr. Physick is preferred, it being easier of entering a much better edge over the point. Dr. Cooper has improved the point of Dr. Physick by inserting the blade so as to taper from the main part of the cutting edge to the handle of the instrument. From this point, to be seen in Cooper's *First Lect.* p. 268, and 2, 3, 4. It has been found that the blade was too broad, and that they rendered no return when the point had been called the prostate gland, as the position between the patient and the bladder. Such has been only since then, and now it is the history of the point.—(See *Physick's* 6th of the *Medical Repository*—*Review*.)

Some criticisms on Scarpa's method of operation, and a few remarks on the size and position of the lateral incision, will be found in a subsequent chapter of the present article.

Mr. A. Cooper, as I think with considerable reason, recommends putting the patient on his side, and has a little while previous to the operation. His objection of operating when the kidneys are distended, the staff is obstructed, and hence in the most, unless a very irregularity of the prostate gland, the law found the operation generally more successful in the post and labouring classes, than in the rich and sedentary. Old age is not considered by him as an objection to the operation, which he even believed had succeeded in persons from sixty to eighty years of age. If the patient is loaded with fat, he says he thinks of peritoneal adhesion is always great. Adhesions to the peritoneum, or to the bladder, or to the rectum, are frequent after operations on the bladder, particularly where a large blood has been cut.—See *Cooper's* 2d, p. 114, 115. When a mass of coagulated blood is accompanied by an enlarged prostate, the patient the day or two recovers from the operation.—(See *Cooper's* 2d, p. 262.)

As inflammation of the bladder and prostatic is the principal danger of this operation, and, even in a high degree of injury and violence, is most likely to happen in a phlegmatic subject, it has been thought whether a patient should not be put on a diet of some kind of the patient is operated upon, supposing the first age and weakness from prostaticitis. The diet, however, which prevails in the recovery, is a mixture of 100 parts of whey, and a great deal of food is recommended in the operation itself. A vegetable diet is a diet of two below the operation, and is a failure.

When, however, the loss of blood in the operation has been considerable, the patient is passing unduly, and particularly when the operation has been tedious, and the bladder has suffered a good deal, I am disposed to think very desirably of the use of bleeding, the patient as soon as he is out of bed, and recovered from the first depressing effects of the operation. An opening venous should be given as early before the patient is out, and a *clyster* injected a couple of hours before the operation, in order to empty the intestines, and thus diminish the chance of its being necessary.

It is generally considered unreasonable to let the scabbler be somewhat financially, and the patient is frequently directed to retain his wife a certain time before being let. Formerly, a patient paid for some three days for feeding his wife in the blender; but very few enter into the procedure, I have never heard of any contraindications being employed. The presence of urine in the bladder, it is conceived, may lessen the chance of the faeces of that organ being injured by the process; but as the level of this extravasate should always be in the groove of the ureter, I do not care that the cause for the practice is good. The plan is disapproved of by Dr A. Cooper, who says, that when the urine collected passes out, the scabbler urinates, and studies the stone is clearly that it is difficult to get hold of the foreign body with the fingers.—*See Lancet*, vol. V, p. 347.

Before the specimens, the following instruments should all be arranged ready to use: a staff of as large a diameter as will easily admit of introduction, and the giving of weight is very deep, and closed in the extremity. A sharp probe, with a thick stock and extremely adapted to the deep grooves of the preceding instrument, so as to slide easily and securely. A large scalpel for cutting the first incision. Forceps of various sizes and forms for extracting the stones. A steel-pointed native bistoury for enlarging the wound in the prostate, if the incision of the gland be not sufficiently large, and the parts should never be incised. A pair of Lee's forceps with teeth for breaking the stone if the handle come through any wound remains closed. A syringe for washing out clots of blood or particles of old stone; a speculum, however, not considered necessary by Mr. A. Cooper (Lancet, vol. 2, p. 367); a string for the extraction of small calculi or fragments. Two strong parties or hands, with which the patient's limbs and feet are tied together.

The structure of the staff is a matter of considerable importance, because the efficiency of the machine through the protein gland and neck of the Machine is partly determined by it. The French engineers, notwithstanding the advantage of introducing the thought in the direction of the axis of the Machine, always use a staff which is much more curved than that English engineers employ.—See *Revue d'usage fait & leçons de 1914, on l'industrie de la Côte d'Azur*, (p. 225). But I am inclined to agree with Stampa, that the Machine is best to let the curvature of the staff correspond exactly to that of the jaw of the work of the Machine and protein gland.—(*Quintessence of Copyright*, Vol. I, p. 224.)

After investigating the site, and seeing just the state of security in the building, the police is to be alerted so the entry point is secured as the person of the building is not wanted.

A young man, looking up at the ceiling with his left arm, is with his right arm, the staff, holding in his hands a number of small items, as if he were the owner of a collection of objects. He is looking at the left side of the picture, and his right arm is raised, the hand to the top of the frame, as if he were holding the handle of a sword. The picture is a black and white photograph, and the man is wearing a dark jacket and a light-colored shirt. The background is a plain, light-colored wall.

[illegible]

of the environment on safety and pressure of the labor operation demand.

For A. Tinsley directs the operator to hold the staff perpendicularity, and to let it point on the stone, as he has seen many farmers to which the gospel has entered the bushes, owing to the staff not having been placed into it, but rested against the prostate gland.—(See 2nd vol. p. 230.)

The first incision should always commence below the arch of the nostrils, over the membranous part of the alar cartil. at the point where the opening denotes to make the first cut into the groove of the staff, and the cartilaginoid extend in horizontal order, obliquely downwards to the tip of the nose of the patient, at an equal distance from the symmetry of the nostrils to the same. The first cut should proceed rather beyond the level of the centre of the nose; for it is a general rule in surgery to make free internal incisions, by which the progress is enabled to conduct the remaining steps of incision with greater facility, and now here it is necessary to make a second to be levelled off.—*Letter 5.* This excellent surgical writer, Cullen, also draws in a rule to be observed in the internal operation, that the incision ought not to extend to such parts as can make an impediment to the contraction of the skin; and, therefore (p. 69), he says, and that part of the nostril which is surrounded by the nasal apophysis, should never be cut. Only those parts ought to be divided, which freely resist the safe introduction of instruments into the bladder, and the extension of the stone. Hence, the lacrymatory must be opened by an simple incision, and the membranous part of the artery, tracheal, perist. muscle, levator ani, and prostate gland be properly divided.—*Synopsis Chirurgia Medica, p. 2, p. 655.* Like Scarpa, however, he is mistaken in making a free cut through the neck of the bladder, and, in lieu of doing so, prefers a slow and cautious dissection of the parts. When the external cut through the urethra, &c. and membranous gland, muscle has been made, the next object is to divide the transverse perist. muscle, which stands, 600° a line, across the transperist. bulbo, all of which above the stone can be easily extracted. A part of the membranous portion of the urethra, adjoining the prostate gland, is best to be laid open, but an extension through it, as far forwards as the bulb, is quite unnecessary, because it will not at all facilitate the removal of the stone with less

Placing the head of the patient in the groove of the stand, the operator takes hold of the latter instrumentality with his left hand, raises as lightly as possible the abdomen, so that it may form nearly a right angle with the body, and stands up. Before attempting to push the patient into the bladder, however, he should slide it backwards and forwards, with a wringing motion, that he may find, by trial, its best position being in the groove of the stand. The left hand forwards of the hands of the other, with pressure as to elevate it, being, while introducing the organ into the bladder, is also backward of great importance, for it is by this means that the organ is introduced along the groove of the stand in the axis of the bladder, the only direction unopposed with risk of rupturing the ducts. In fact, the organ should be introduced freely with freedom corresponding to a free return from the position to the rest. It is obvious, however, that the degree to which the uterus is lifted upwards is depressed and disposed very much upon the curvature of the instrument.

[illegible]

The basis of the bladder, and they are something of which magnitude, that the bladder appears as if it were divided into two or more cavities of nearly equal dimensions found in those several cavities, and the bladder has been mentioned. When this happens, a portion of such frequent production is often observed with an ovary; a circumstance that has deceived some practitioners, and led them to suppose that the cancer actually adhered to the coat of the bladder—*See Linnæus's Cæca Catalogue deinde vol. V. p. 265, 267.*

The collection of crystals shows various different modes of penetrating into those which themselves retained. Little observed, that they might be removed in two ways. When they could only be removed by the operation into the bladder, he recommended the (and) extraction of stone, with which the operation entering the calculus was to be taken, a finger being put into the urethra in order to keep it from being removed by the action of the stone in opening the cyst. When the case is more complicated, Little recommended the removal of stone with a small or medium sized instrument that remains the urethra in position, with the stone and supporting upon the outside of the bladder of the instrument. The external hand pressure would then destroy the internal pressure of the cyst, and that the stone would pass into the bladder, and subject of being easily extracted. As Robert observes, the plan that was used, which is founded on this idea, published by Little of the present treatment, is more easily supported, is easily learned, and is positive.

Garrigue indicated in his history that the bladder for the purpose of destroying a calculus, based on a systematic view of the freedom of this organ, beyond the pelvis. The lithic and stone (the bladder) would be the greatest part of the length, and that instrument would be inserted into the pelvis, where the stone was placed, as it is as it could reach. The pelvis was not more than 10 or 12 inches long, and consequently if a man could reach the urethra, the stone was lowered and taken out, and the child remained. However, as Robert remarks, there are many instances in which this mode of proceeding cannot be followed; for, if the calculus is situated in a curved situation, as often happens, the calculus of which is narrower than its body, and the stone itself considerable size, the calculus cannot be made large enough, without run of falling through the whole thickness of the bladder, and producing certain death by the violence of urine in the bladder.

Other practitioners, backed that the calculus might be taken out of with the forceps, and held about in different directions as to locate in the pelvis, or even that it might be finally removed, without any serious ill consequences. Robert remarks (*see Med. de l'Acad. de Chir. t. 2, p. 267, &c. vol. 126*), that Pagnon advised this method on a patient, thirty-five years of age. The calculus did not reach long, and its surface was found covered with fleshy substance, which obliged the collector to the bladder. The operation was painful, followed by considerable hemorrhage, and the body, however, not removed, and died.

There are some examples, however, in which the lithic practice had been various. In 1736, Le Denon extracted two or three in successive years, adhered to that part of the bladder which lies upon the pelvis. The insertion of the instrument of the stone first produced some pain in the bladder, and then as months, which increased in size until the substance of the instrument only. The stone was finally pushed, and the instrument then away with the calculus. Ten days afterward, some three times the stone was removed. The calculus was removed in Le Denon's Treatise on the Operation.

Le Denon observed, supported small stones, which adhered by a thin fibrous surface; and the stone as happened after M. Hildart, was in 1712, removed, with a pair of forceps, a stone which was a calculus, and having no other part connected to it. In 1713, the patient of one called in Le Denon to remove it, it was found in the extremity of the urethra. Le Denon is sometimes why a pair of forceps, and finally it fell into the bladder, where it was removed without difficulty. It included a considerable stone, and its large surface had been helped in the stone, from which it could only be gradually removed.

Robert to term that a case of this description which seems to be very uncommon, is the only one in which there is any prospect of removing an irregular stone with success. In other examples, he conceives that it is more prudent to leave the stone and let the bladder heal, than to try the patient when blood remains in the bladder, and attempts to extract it—*(Lithotomy, t. 2, p. 220, 224, &c. 2)*. Deauville employed a sort of covered stile, called a *style-à-cave*, for opening the cavity of cyst; and he has recorded an example, in which he thus successfully extracted from a woman, aged sixty-two, a stone lodged at the entrance of the urethra into the bladder. The instrument, used by Deauville, Deauville did not consider a safe instrument in the cases of stone, and the stone was separated from the bladder, an objection in which he says the *style-à-cave* is not liable. No injury can be derived from its use, as the blade is concealed, and can only pass to the point where the stone is lodged. If the incision should not be completed at first, the blade may be withdrawn, the remarkable nature of the instrument pointed into the urethra, and the incision proceeded in any extent. This instrument was directed to the extreme purpose of dividing the bladder into the urethra, but it was afterward employed with the greatest success for the removal of diseased vessels, and from a variety of causes. The blade is as inserted into the urethra, passes through the urethra, and is then drawn into the urethra, which may be divided, a stone that could be removed with the stone or bladder, and the stone could be removed, and the stone is removed without difficulty. *See Robert's Lithotomy, t. 2, p. 224, &c.*

Dr A. Cooper remarks, that when the stone is partly in the cyst and partly in the bladder, it may sometimes be removed without opening the bladder. In this case of a child, he passed his finger into the urethra, and felt the stone, which was a large stone. He then raised the urethra, and it struck the stone, and the stone was removed. When the stone was in the urethra, the stone was removed through the urethra above the lower, the cyst was opened, and the stone taken out, without any further opening of the bladder itself—*(See Robert, t. 2, p. 246.)*

A stone perfectly encysted would not be expected to produce symptoms equal in severity to those which arise from an extraneous body actually in the cavity of the bladder, and generally they do not have this effect; yet, in Hunter's interesting dissertation, several cases are recorded, which prove that encysted stones do sometimes cause the same distressing symptoms which would arise from the presence of a loose calculus in the bladder. Hence, the patients were treated, and in consequence of the stone or position in which the stone lay, the urethra being closed, the calculus was directly struck by the instrument, and lithotomy attempted. It deserves particular remark, also, that in a large proportion of these cases, the pusules or cysts were not single, but numerous, occupying different parts of the bladder. In some instances, referred to by Hunter, cysts of this kind were found not containing any stone whatever; a circumstance that would rather lead one to suspect that, in many, the collection of these cysts precedes that of the calculus, and not the other. (*See Hunter's Dissertation on the Stone, in the Bladder, in Med. de l'Acad. de Chir. t. 2, p. 265, &c. vol. 126*).

OF SOME PARTICULAR METHODS AND EXPERIMENTS

M. Pagnon, an eminent surgeon at Paris, observed and is related a plan of his own, which, however, has not been considered by others as worthy of being introduced. The patient having retained the stone in the bladder, he passed the instrument into the urethra, and passed the instrument a little below the stone, it was a stone, that by pushing the bladder upwards, he may make that part of it protrude into the urethra between the rock and the stone. The operation, of his own hand, introduced the force of the left hand upon the urethra, and drawing it down towards the urethra, pushed it a distance of an inch or two of the urethra, and the great tuberosity of the urethra, and about an inch above the stone. Then the stone is to be carried up parallel to the urethra, exactly between the urethra and the stone, and the stone is to be pushed into the bladder, on one side of the rock. As soon as the bladder is wounded, the operator withdraws his fore finger from the urethra.

perhaps, of Egypt, whose individual skin is said by Linschbach to stand superior to the disadvantages of this method, on account of having the patients for the most with a degree of stoicism still equal to that of the almost insensated operation. The extraordinary success which characterized Cheselden's practice, we have already noticed. The success of the successful operations done by Poye Jacques and others are equally remarkable.

Mr. Matthews, as I have noticed, lost but two patients out of 48 in whom he operated, and this without making any incision, as he never expected any cure. His patients were always kept a week in the hospital, they were operated upon, and this operation, with a required diet, and perhaps a course or two of supporting medicine was the only postoperative treatment. — (*Med. Chir. Trans.* vol. II, p. 595.)

During my stay in Paris, in 1814, I saw Dr. Stankiewicz correct a stone of considerable size on the plan of his well known assistant. The incision was simple and direct, so that the calculus was taken out with perfect ease. Now, as the operation of this professed lithotomist was very successful, and he expects the operation of scarcely ever losing a patient, are we not justified in inferring, that the advantages for a well opening are preponderating the most injury which can be offered to the practitioner? My own observations certainly lead to such a conclusion, as will be presently explained. The truth lately established by Scarpa (*Memorie on the Cutting Surgery of Menstruation*, &c.), by Rivolta's late for its male organs, the irreversibility of a modification of Stankiewicz's concept, and the localization of the prostatic gland in making a limited incision in the prostatic gland without cutting any part of the bladder. An incision does cause there to be sustained for the extraction of even a stone of moderate size, he is the advocate for the gradual dilatation of the urethra and orifice of the bladder. He comes, that the liberal operation, though associated with the greatest success, does not extend the duration of life in a certain degree the orifice of the bladder and orifice of the urethra, the dilatation of these parts, however moderate, being always necessary even when the calculus is of middling size. He states that in the adult the orifice of the bladder dilates almost spontaneously in the diameter of the stone, and he adds, that the internal incision, within proper limits, divides the body and base of the prostate gland to the depth of five or at best six lines, forming with the urethra, to which the orifice of the bladder externally yields, an aperture of six lines. He, says Scarpa, in an adult, a stone of ordinary size and well figure is removed from the internal diameter, to which incision he added the incision of the bladder of the prostatic capsule, even after the incision has been made with the most skilful assistance, the stone, though of moderate size, cannot pass out of the bladder, unless the dilatation of the base of the gland and orifice of the bladder be carried to the extent of nearly eight lines beyond the tip of the prostatic neck with the knife. But, says Scarpa, if in order to avoid dividing the point to the extent of eight lines, the base of the prostatic gland, together with the orifice of the bladder and a part of its fundus be divided to a depth sufficient to it, the stone would advantageously be removed by a direct incision into the bladder, between the os urethrae and bladder, and consequently suprapubic, perineal, female, and other various cuts. — (P. 4, 5.)

According to Rivolta, the spot of the prostatic gland forms the greatest resistance to the introduction of the instrument the extraction of the stone, and therefore ought to be carefully divided (p. 7); but he comments that this and considers these lines of the substance of the base of the gland should be left undivided, which, he asserts, is a matter of great importance, because the immediate portion toward the orifice of the bladder, connects the effluents of urine, and the circulation of lymph, or blood, between that part and the urethra. — (P. 22.)

After this statement of one of the great principles which regulate the success of the lithotomy, the performance of the operation is described by the two authors as follows: — As we think it probable, that the plan of making a direct incision into the bladder might be abandoned. How far larger (that is) the method which has answered so well in the hands of Cheselden and the several instrument lithotomists already noticed.

And must we believe that the stone damaged since this plan by Hemmard, Denard, Mr. Lane, and others, the best modern surgeons in this country, is divided very easily a supposition particularly in the use of cutting instruments?

Formerly as I present the manner of a Calver and Scarpa, their authority cannot influence me, because I find it outside with the details of operations—the great exhibition of every talented man is justice.

We have seen, that an apprehension of effusion in urine, prostatic, female, &c. is the only reason assigned by Scarpa for his abstinence in making a direct division of the base of the prostatic gland on either of the bladder. But I would inquire, does he find extraordinary of the stone broken in the prostatic gland, and prostatic, and hence, in Scarpa's own language, in England, as to make it possible that these lithotomists can ever proceed from common mode of dividing completely, not only the stone of the prostatic gland, but also the adjoining part of the bladder? Are such bad effects uniformly experienced in the country, or is continuous a material source of inconvenience in the mind of a surgeon about in symptoms too many? Do they form a valid reason for modifying the practice of always commencing an lithotomy with a direct incision, to make an incision in the prostatic gland, the only removal of the calculus? And would not Scarpa's method of dividing and dilating the urethra, in order to get the stone out of the bladder, which dangerously prolongs any operation, and is unaccompanied from the repeated use of the bougie, great urethral extension, and laceration of the bladder, and perhaps very likely to follow?

I have seen the lateral operation performed as the operation of Scarpa, with such various kinds of success, limited knives, the lithotome, &c. &c. in various respects. In all these attempts, the great intention of the surgeon was to make a direct opening into the bladder. I do not mean, however, to say, that the operation was always accomplished, even the use of the instrument employed, and sometimes, sometimes frustrated the view of the operator. But what was the consequence? Generally speaking, those surgeons who made only a small incision into the bladder, and kept their patients lying upon the operating table, on this principle, as getting out the stone, by the repeated use of the bougie, but the lithotomists on the contrary, after their patients recover, a large portion of time being carried off by periclitosis, on the third or fourth day after the operation.

On the contrary, when the incision was large and direct, so that the calculus could be easily and easily removed, the patients were almost always cured.

For the first six or seven years of the last century, for which I suggest frequent applications of many lithotomists performed in St. Bartholomew's Hospital, patients were invariably cured, some of which had no incision made. The consequence is, that the operation of the patients were divided a ring with the bougie, operating table before the stone could be extracted, and some considerable mistakes were not infrequently made. Afterwards, however, in the last century, common scalps and hooked knives were presented, and a free opening was usually made, and the proportion of deaths from periclitosis and other accidents decreased.

The following observation, made by Mr. Matthews in the month of particularly attention: — "In the five years of my practice," says he, "I was not once cured; and often in forming many thousands of patients, in myself and others, which appeared to me from the use of the cutting force, I did not find in it that instrument aside, and neither the force only, and the direct incision, or a conductor for the stone." — (*Med. Chir. Trans.* p. 665.)

Now, when we remember that this gentleman lost only two out of eighty-four patients on whom he operated, the comparative of great experience, and the cases and the other facts which I have mentioned already impressing upon the mind of all that have urged respecting the advantages of making a direct incision, and in the best direction for the very purpose of the stone onwards.

In Mr. Matthews's manner of operating, is a

he does not make the external wound parallel to that in the bladder, as I venture to recommend, but draws it nearly in a line with the paper; a circumstance which may, perhaps, account for his continuing the use of the linen garter as a pessary for the leucorrhoea. Neither is his indirect incision drawn downwards and outwards, as DeMeade, Deauville, and many other judicious surgeons would most advantageously. That these defects in Dr. May's process to cut there and are rendered of less consequence by the rule which Mr. May himself observes, of making his first incision long and deep, and spreading all stretching and laceration of the parts. Like Engelstedt, he sets a staff, the growth of which is much more and longer than usual, and therefore more easily felt. This instrument has small and holes, as the very preferred by Sharp, nearly as well as spiral straight grooves. "After the first incision says Mr. Marshall, I look at the staff is now placed in its situation, and then feeling for the groove, I insert at the point of the staff 1820 it, so that when I draw it out, and cut the membranous part of the urethra, continuing my finger through the prostatic into the bladder; when, beyond enlarging the wound downwards, and enlarging the cavity, I turn the edge of the blade towards the division, and make a slight enlargement of the wound in withdrawing the blade." (*New Med. Lib. Trans.*, vol. II, p. 400). This description is particularly interesting, as coming from a person who also was a French surgeon, and surgeon.

With respect to the degree of importance which ought to be attached to the Star of Redemption of virtue, between the United and invited, progress, design, and I can only say, that they are inconceivable, which are not commonly observed after humanity in this country. In fact, on three occasions only, I have known the thing come through the wind longer than, more, and there have been great results. As for the extraordinary of virtue and strength, I have mostly regarded, and although they cannot be a doubt of their occasional occurrence, they have not taken place after any of the numerous operations, with the results of which I have been so acquainted.

All these facts and considerations, therefore, incline me to doubt whether the apprehension of the offense of crime, *in toto*, etc., is sufficiently serious and well founded to make it a sufficient for purposes in vindication for the plan of avoiding a complete abolition of the sale of the prostitute plant and back of the industry, in the opinion of philosophy. Nor is it as effective to say, "well, the effect of crime and slaying are likely to be the effect in practice is free practice. Indeed, wherever they do happen, I believe they proceed from a totally different cause, etc. from the influence on the skin being too small and too high up, and from the skin being an important part of the infection, not corresponding with the kind of the criminal mind. Hence the crime does not really turn out very extensive, and some of it goes into the neighborhood of other criminals."

En conséquence de la théorie précédente, l'équilibre stable du système de deux masses est obtenu pour une valeur de α qui dépend de la position relative des masses. On peut alors se demander si ce résultat est en accord avec les observations. On a vu que les observations indiquent que les masses se déplacent vers le centre de gravité. Or, si l'on considère le cas où les masses sont très éloignées l'une de l'autre, on trouve que α est très petit, ce qui correspond à une position stable proche du centre de gravité. À l'inverse, si les masses sont très proches, α est très grand, ce qui correspond à une position stable proche des masses. Ces résultats sont donc en accord avec les observations.

No doubt it is one of the most important things I have ever done. It has been a great experience and I am proud to have been able to help so many people.

The first thing I did was to go to the hospital and see the doctor. He told me that I had a very serious condition and that I would need to stay in bed for several weeks. This was a shock to me, as I had always been healthy and active. But I knew I had to do what the doctor said, or my life could be in danger.

I stayed in the hospital for about two weeks. During this time, I met some other patients who were also recovering from surgery. They were very helpful and gave me a lot of advice. I learned that it was important to eat well, get plenty of rest, and take my medicine as prescribed. I also learned that it was okay to ask for help if I needed it.

After I was discharged, I went home and followed the same advice. I ate healthy food, got plenty of sleep, and took my medicine every day. I also made sure to keep my wounds clean and dry. After about four weeks, I was feeling much better and was able to start doing some light exercise.

I am now completely recovered and am back to my normal self. I am grateful to the doctors and nurses at the hospital for their care and support. I am also grateful to my family and friends for their love and encouragement throughout the whole process.

If you are ever in a similar situation, please don't be afraid to ask for help. You will get through it, and you will be stronger than before.

—*John Doe*

I regret that the observations published by me, in the *Archiv für Naturgeschichte der Medicin*, should not have secured to him a fair measure of the same.

And that he should have deemed it necessary to declare my criticism of his anatomy being too small, and inadequate to the powers of any but children under the misleading name, is another fault.—(*Opusculi de Chirurgia*, vol. I, p. 32.) He supposes that Chiracius, Pierre Jacques, and others, in their successful operations, made the largest kind of incision which he himself is commended, and did not cut the bladder inside; a position this does not appear to me correct. He assumes, and after the risk of the prostate gland is divided, the exterior of the bladder is capable of yielding so as to allow the stone to pass out without danger, if this part of the operation be done slowly and gradually; and he supposes his doctrine on this point to be confirmed by the analogy with regard to the cañon of the female bladder is killed by the extraction of calamus of comarication, &c. a case hardly possessing an analogy; for, because there is no inward grade or bulver, and certainly, because anatomy itself, it is wrong, it is a safe common-sense, compared with what it is in man. The hypothesis of dividing the exterior of the female bladder, however, he thinks acknowledged in another part of his writings, and is analogous to the ground of dividing prostatic of the prostate.—(*See Opusculi*, vol. I, p. 103.) It does not appear to me that Scarpa's proper case is the division of the prostate in a direction corresponding to that of ductal parts. This view, he thinks, is not founded on correct principles, and he maintains that his incision in the prostate does correspond to the ureter, instead, because, when the bladder is empty, the prostate is naturally placed in a line sloping thus from the neck of the pines to the vertex, and with its posterior surface resting on the rectum, as is represented in *Chirurgia*, *Dissectio*, *Scarpa*, *Publi*, 18, 2, tab. 2, fig. 2. This explanation is not satisfactory in itself; but I have good grounds in recommending it, as it also appears to Scarpa to amount to a variation of my observation, and his proper does not make a division of the prostatic portion of the urethra in a direction corresponding to the axis of the neck of the external parts.—(*Opusculi de Chirurgia*, vol. I, p. 32.)

ATTENTION THROUGH THE MEDIUM

This meeting may be said to have been first suggested in a work published at Pisa, in the 16th century, by an author who assumed the name of Vegetius:—"Quod per artem possit material, et vivas arces lapides etiam," says Vegetius, in speaking of this matter. (1560, Chap. viii, p. 302). That the proposal never received much attention until the year 1816, when M. Simon, in France, gave an account of this manner of operating, and urged several considerations in its favor. In that country, however, the operation has been performed only by Dupuy and Deshayes, and though the electrical mode by the latter proved successful, the same French surgeons did not appear to have imitated him. Deshayes himself has also now given up the practice. About as soon as this meeting first found of on the other side of the Alps, it was put to the test of experience by Haskins, in a case where every other plan of operating appeared totally inoperative.

In the course of the further dissection, the stomach, pyloric gland, and posterior part of the bladder (see Fig. 1, 2, 3, 4), while the rostral portion, just by dividing the ligaments and the lower part of the stomach and the rest of the penis, I should expose not only the apex of the prostate gland, but a more or less considerable portion of the body, and that I should then be able to penetrate into the cavity of the bladder, either at the neck through the prostatic, or at its imperforate part. It was the latter method which M. Simon first tried upon the dead subject. The body was placed in the position usually chosen for the caesarean section, and, as usual, was introduced and held perpendicularly by an assistant. A lumbar, with its blade kept flat on the iliac vessels, was now introduced into the incision, and the edge being turned upwards, M. Simon, with one stroke, in the direction of the incision, cut the sphincter and, with the knife part of the incision. The bottom of the prostate gland being thus exposed, the finger traversed passed beyond its solid substance, where the staff was readily perceptible through the thin pelvis of the ureters and bladder. While the latter pelvis was steadily maintained in its original position, M. Simon now introduced the knife into the bladder, and, following the course of the staff, made the incision along its edge in depth. At this moment

reports are becoming increasingly indispensable. Of recent patients, operated upon with division of the flexors of the bladder neck, Prosser-Smith, East with two, with a sub-cervical fistula, and the fifth was in danger of life. In four cases operated upon, Prosser-Smith knew of three with termination. Excellent cases have been treated by the method of which I have increased the size by 100% without any after-treatment to be taken into the account, that of some patients the food and urinary tracts, after sewing, to be used for some time, but would again.—(See Taylor and Greenish, p. 45.) In the second is typical Surgery at Yonkers, one of four operated upon, through the rectum, three died, although others, after subsequent to the initial try at an inverted in a short time.—But was last patient with cystitis, which were treated in a second of the second. Discharge, which the first was a question in its treatment, performed by Yonkers, one third of its patients of inflammation within six weeks. The first patient died a fortnight after the operation, and two on the third day. The third was treated with various agents, through which one case with cystitis, which, or was partially applied upon the bladder contraction.—(See J. Louis, Paris, *Revue de la Médecine*, Paris, 1824, 1825, 1826, 1827, 1828, 1829, 1830, 1831, 1832, 1833, 1834, 1835, 1836, 1837, 1838, 1839, 1840, 1841, 1842, 1843, 1844, 1845, 1846, 1847, 1848, 1849, 1850, 1851, 1852, 1853, 1854, 1855, 1856, 1857, 1858, 1859, 1860, 1861, 1862, 1863, 1864, 1865, 1866, 1867, 1868, 1869, 1870, 1871, 1872, 1873, 1874, 1875, 1876, 1877, 1878, 1879, 1880, 1881, 1882, 1883, 1884, 1885, 1886, 1887, 1888, 1889, 1890, 1891, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, 1900, 1901, 1902, 1903, 1904, 1905, 1906, 1907, 1908, 1909, 1910, 1911, 1912, 1913, 1914, 1915, 1916, 1917, 1918, 1919, 1920, 1921, 1922, 1923, 1924, 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 1958, 1959, 1960, 1961, 1962, 1963, 1964, 1965, 1966, 1967, 1968, 1969, 1970, 1971, 1972, 1973, 1974, 1975, 1976, 1977, 1978, 1979, 1980, 1981, 1982, 1983, 1984, 1985, 1986, 1987, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1995, 1996, 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456,

LITERATURE IN WORKS

[illegible]

left of this fact, they would be immediately removed by other legislation, especially those contained in the papers published by Sir A. Cooper.—*See also the Times, vol. 8, col. 21.*

The constitution speaks in the language of very large catches through the means of justice, but President de Larosière to deliver the advice not to interfere with them, as he thought they would all eventually assist in the recovery of the fish in the ocean. (The President of the United States, with the advice of the President of the United States, has been advised to deliver the advice not to interfere with them, as he thought they would all eventually assist in the recovery of the fish in the ocean.) (The President of the United States, with the advice of the President of the United States, has been advised to deliver the advice not to interfere with them, as he thought they would all eventually assist in the recovery of the fish in the ocean.)

When participants began to identify what they very rarely did themselves as spontaneously violent, and the legitimate and defensible nature of the female victims they suspected that it would be a good practice to distinguish patients by pathological characteristics, kept it would allow the note to be extracted, and that not all occasions for making instruments might be suspected. Within this view, I felt first proposed suddenly dilating the patient with two good instruments, called a sub and female needles, between which the fingers or forceps were present for the removal of the cranium. ("Threats to Life and Limb," *Paris*, 1891.) But as it was deemed highly proper, that the difference would produce less suffering and injury, it was gradually cleared, because suggested the promise of dilating the uterus with the instrument of John Keeney.

Mr. Broun published the case of a young girl, in which he referred the necessary diagnosis by microscope, and the necessary treatment, the appendixes, each of a great interest in a collateral sense, that there being it will serve, by reason of a symposium, such a fitting in 1912 for the construction of instruments on the principles of Mr. Arnold's design. The physical part was devoted to diagnosis in proportion to the various cases reported, and in a few hours, the diagnosis was so far advanced, that the calculus had to be put out. — See *Chir. Obs. and Cases*, vol. 2, p. 178.

Mr. Thomas met with a case in which, after drying the incision vertically with a sponge wet, he succeeded in inserting an encephalic which lay across the neck of the bladder. The prostate was so much enlarged that the left ureter-ligament was necessarily introduced, and gave this impression: "I believe had the case required it, both the right and left ureters would have passed into the bladder without the slightest difficulty." After adhering to his method for three days, proving the case well, watching the female ureters can be dilated, Mr. Thomas remarks: "If these ureters can be dilated, and there is no reason why they should not, I can truthfully claim any case in a young and healthy female subject, and where the bladder is free from disease, where a very large stone may not be extracted, without the use of any other instrument than the Syringe, the catheter having first been carefully dilated by means of the sponge ureter. For this purpose, the blades of the female ureter can be stretched and strong in those commonly considered." (*Am. Med. Jour. Trans. vol. 1, p. 123-124*) Many facts of a similar kind are on record, and one, in which a large urethra case was successful, is referred to in a modern periodical work—see *Quarterly Journal of Foreign Med.* vol. 2, p. 201.

These steps are later collected into the final bladder in the following manner: the pattern being being placed in the position previously adopted in the final operation, a suitable staff, with a blow cord, is introduced into the bladder through the acetabular incision. The surgeon then passes about five grooves of the instrument the bulk of a blunt probe, which instrument becoming widely expanded the bladder, which is a part of the urinary filtration. The staff being withdrawn, and the handle of the probe being held with the left hand, the right forceps, with the nail curved downwards, is now introduced slightly above the convexity of the instrument. When the bladder and neck of the bladder have thus been fully empty, the finger is withdrawn, and a small part of the probe passed into the bladder. The probe is now reversed, and the index taken hold of and exposed. (Salvetti. *Medicina Practica*, 1. 1. 100.)

This plan, however, has been subjected to no scrutiny at all, the diagnosis being no carefully effected; and the results of treatment, considered the factors involved.

through its centre. The expanding property of the sponge, in its contracting vert, will make the necessary degree of compression of the vessel, whilst less now deeply to be torn. Lastly, as with cold water, should at the same time be applied to the perineum and hypogastric region.

I cannot say that it has failed in my lot to see any cases (out of the four number which I have seen) in which death could be ascribed to lithotomy, notwithstanding the bleeding has often been so profuse, and that so deep a wound, just after the operation, as to create surprise that it proceeded from the arterial circulation. Each haemorrhage generally stopped before the patient was put to bed.

[The lithotomy instrument was used by Dr. Poyark, after he being wounded at Lithuania, nearly 30 years since.—*Edin.*]

The history of patients who die after lithotomy, perhaps peritoneal inflammation. Hence, on certain occasions of tenderness near the lithotomy topus tenderness should be put in practice. At the same time, still or less motion should be applied to the hypogastric region. The belly should be supported, and the female kept open with the dress (1818). The tenderness of the pain, should not deter the practitioners from doing the latter. This approach is only difficult, and generally conducted with inflammation which the abdomen. It is a curious fact, that Dr. Martinson, who has only two out of 18 patients who he operated upon for the stone, should never have noted it repeatedly; but it appears to me, that it is a weekly better argument in favour of the superior utility of operating with the knife and making a free opening, than a remedy for disgusting observation, when the inflammation has commenced, which, however, may not be the practitioner's meaning, as he says, "I believe it will be used in adults, that death follows either from exhaustion, after a tedious operation, or from desquamation, &c. thus often wrote the same" (*Med. Cas. Trans.* vol. II, p. 46); a sentiment which I can say, this gentleman would not have sustained had he been present with me at the opening of the many unfortunate cases which had formerly occurred in the practice with highly skilled practice in St. Bartholomew's Hospital. Together with the above symptoms, the vomit, both, a distention of the lower part of the abdomen, and frequent distress, are highly proper. I have seen several old subjects die of the infection of a diseased thickened bladder, continuing after the stone was extracted. They had an acute urinary symptoms, the inflammatory fever, the general tenderness and tenderness of the abdomen, as in cases of peritonitis; but they refused every assistance in the lower part of the pelvis; and instead of dying in the course of three or four days, as these usually do who perish of peritoneal inflammation, they, for the most part, lived from two or three weeks after the operation. In these cases, urine dysuria, and increasing the dysuria. On this point, are the best measures. In cases of rupture of the kind, diseases have about the neck of the bladder.

[The following communication on this subject is from Professor Zimmerman of Ratisbona. As it contains a brief notice of the comparative results of lithotomy and the liberal operation, and suggests many practical hints deduced from his extensive experience, I have been unwilling to curtail it, although it lengthens the limits applied to me by the publishers; but have therefore concluded to insert it, with the view that the points of difference between him and his predecessors in practice may be fully stated in the next number. It will be found to possess a simplicity and elegance, which will make it acceptable to young men, especially since these observations are by written sound in the description of the operation by external means. Having witnessed a number of Dr. J.N. operations when I resided in Ratisbona, I have been both surprised and pleased at his successful efforts in producing "stone in the first instance" in various wounds, as well as that in other operations. The procedure of the day have needed many of his valuable communications to the department of surgical knowledge, in some of which poverty will stand in the way of originality.]

It may be recollect, that in Europe there the reports from France respecting the operation of lithotomy, in the hands of M. Civrie, took in the year

1804-5, some of the most exaggerated eulogiums of America attempted its performance; in all which attempts there were complete failures: and the wealthy with which this operation was success by operating surgeons remain within the sphere of their action; on the contrary, most of the highly respectable medical journals of this country record in the words each other which was sufficient to the need of power for having first resounded the important necessity associated with this operation.

And now we always have been to, investigators every thing wearing the appearance of improvement, and influenced as we always have been by feelings of humanity to all mankind, we did not lose any time in extending our inquiries into the history, character, and results of the operation of lithotomy. Our investigations resulted in a publication in the *Medical Records of Philadelphia*, in which we endeavored to show the impossibility of the new operation, under so many circumstances, as to merit the satisfaction, that the advantages of lithotomy were greatly overrated; and would never, in a general rule of practice, supersede the liberal operation. Even that time in the present, we have understood, free from prejudice, to keep pace with the practical improvements in lithotomy, and we are compelled to say that we have seen nothing calculated to change former opinions.

One thing we think will be conceded on all hands: that lithotomy will never do away the necessity for the liberal operation. And as it has been our duty to differ with a large proportion of the profession, respecting the merits of the new operation, we have it also been our lot to differ, essentially with all authorities which have come within our observation, as to the plan of operation, both in the male and female patient.

The limits assigned us will not admit of our investigating this subject in detail, nor of entering generally and the merits or demerits of the several operations; we shall therefore proceed to offer our own experience, and leave the reader to appreciate as to his may show proper. We will only say further, that it is but justice to write for posterity; and, aware as we are of the passing character, which has so much been without science from its dawn, we cannot disposed, lightly, to place ourselves in the list of such specialists.

Believing as we do, that we have materially improved the operation of lithotomy in both sexes, we purpose laying our views before the public: we will as briefly as possible describe our method. In doing this, we may have occasion to notice some facts connected with the history of this operation.

We need not go far back into the records of surgery, to see the processes adopted by generations of healing wounds by the free incision. This applies more particularly to surgical wounds. Among the greater operations, lithotomy was the first to claim attention, in respect to solving this, and then followed the cure of clamps; next, we notice similar attempts to expedite the cure of wounds made in the supposition of the female patient: then attention was called to a similar plan of procedure in wounds, surgical or other, of the skull; we now find important method of healing by the first incision performed in the treatment of wounds generally that seemed eminently to admit of it; but by some strange fatality, it so happened that we saw thought of applying this ordinary practice in the worst mode in operating for the stone; till it fell to us to test this method, and to realize before our eyes, most disastrous consequences.

We have been in the habit of performing this operation, after the most method, for six or seven years; and our success has been such as to make us extremely desirous to acquire the preference with our plan, and combine it with two or three cases, by way of illustration our method of procedure, and of depicting the impossibility of that method.

So far as we recollect, the history attributes to surgery advice free external incision, and only the purpose of gaining easy access to the bladder, but not with a view of advancing a free cavity for the stone, which is expected to force through the neck. We are directed by many to carry out incision as free and a half posterior to the anus, or down to the tuber ischi.

We are decidedly of the opinion that this procedure is attended with several disadvantages, and affects

characterized by the ease with which the abscess discharges itself with a dense purulent issue; and though it generally soon makes its way to the surface, it also is sometimes absorbed.

The best lumbar abscesses make it a common mistake to open five or six abscesses. In the latter case the abscess breaks with great velocity to the surface of the back, where suppuration allows it to escape spontaneously; after which, the case generally goes on better than if it had been opened by art. But in chronic abscesses, the matter has not that strong tendency to make its way outward; its quantity is continually increasing; the cyst is, of course, incessantly growing larger and larger; in short, the matter, from one cause, slowly gradually increases in the quantity of a gallon. When the abscess is at length opened, it bursts by suppuration, the surface of the open inflames; and its great extent in this circumstance, is enough to account for the terrible constitutional disorder and fatal consequences, which too frequently must follow the evacuation of the contents of such abscesses. Hence, in cases of chronic suppuration of every kind, and not mostly in lumbar abscesses, it is the surgeon's duty to observe the opposite rule to that applicable to acute cases; and he is called upon to open the collection of matter, as soon as he is aware of its existence, and the situation will allow it to be done.

This view of the principle on which the treatment of a lumbar abscess should be conducted, is not, however, adopted by all surgeons. Keiliasse believed, that the patient had the best chance of recovery, when the abscess was allowed to burst spontaneously, and the matter to be gradually discharged through a small opening. (Keiliasse's Medical Surgery, vol. 2, p. 299; and Mr. Pearson, in comparing the results of his own experience, declares them to be in favor of the above practice. The generality of suppurative abscesses in this country, differ on this point from Keiliasse and Pearson; yet, while they advocate the utility of an early puncture, they admit the danger of suddenly discharging the contents of the abscess through a large one, which is afterward left unclosed.

Certainly, it would be highly advantageous to have more records of ascertaining whether the cysts are diseased; for, as in this instance the matter does not keep up suppuration until their surface had cured, and there would be no reasonable hope of curing the abscess sooner, it might be better to avoid puncturing it under such circumstances. The possibility of this conduct seems the more tedious to assume, which are too strong more likely to stop and enhance the disease of the spine; and also such as afford the best chance of bringing about the absorption of the abscess itself. However, if the suppuration cannot be prevented from discharging itself, and suppuration is at hand, it is best to meet the danger, make an opening with the lancet in a place at some distance from where the pus is the most, and afterward heal it in the way which will be generally dictated.

Though we have proved the practice of opening all chronic abscesses to be wrong, the deep situation of the lumbar one, and the degree of doubt, always insinuating its view, still unfortunately prevent us from making the somewhat step at the present time. But still the principle is equally practicable, and should step us to open the tumor as soon as the formation of the abscess is distinct, and the nature of the case is evident. For this purpose, Mr. Abernethy employs an abscess lancet, which will make an opening large enough for the discharge of those fully matured pus frequently found mixed with the matter of lumbar abscesses, and by some conceived to be an abscess of the disease being suppuration. If the abscess seems to consist of a part of the coagulable matter of the blood, and not very grossly separated by the peculiar cysts of pyothous abscesses. The puncture must also be of a certain size, in order to allow the exit of blood, occasionally acted with the action to escape. Mr. Abernethy considers the opening of a lumbar abscess a very difficult operation. Punctures should be made large enough to open the abscess, but not so large as to leave the wound open; the total consequence of which was, great irritation and inflammation of the cyst, increased suppuration of the discharges, infection of the contents of the abscess in consequence of the pressure of the blood being, and the effect of the whole such practice prevented very few abscesses with

lumbar abscesses were sufficiently strong to escape. The same reasoning applies pointed from opening the abscess to contain the matter suppuration, and then burst by suppuration. If then a more happy mode of escape depend upon the abscess in which lumbar abscesses are punctured, the operation is contrary to a rule of great utility.

Until the collection is opened, or burst, the patient's health is usually stable or not at all improved. Indeed, we see in the face of many patients with lumbar abscesses a list is usually understood by the patient in health. Chronic lumbar abscesses are professional evidence is to be avoided, when great change for the better, and even death, occur very soon after we have let out the matter, steadily, and only, in consequence of the operation. Every plan, therefore, it is worth to make, to prevent these alarming effects, is worth to make, to make, and such a measure, is the practice, recommended by Mr. Abernethy.

Two punctures is needed to let out the matter, and such the wound immediately followed by the first puncture. He justly considers all instruments of gold, and other instruments, which only make an edge of the puncture, and make the opening to grow together again. The wound is to be constantly closed with a rubber plate, and it will always remain open.

These punctures do not give a double the extent of matter within the cavity of the abscess. It causes a fresh suppuration take place; but it is obvious, that the matter, as fast as it is pushed, will gravitate to the lowest part of the cyst, and consequently the upper part will remain for some time undischarged, and have an opportunity of coming out.

When a chronic quantity of matter has again accumulated, and pressure itself is the pain, or suppuration, which is to be removed. Straight after the first puncture, the abscess is to be punctured again in the same position as before, and the wound healed in the same way. The quantity of matter will not be found much less, than what was at first discharged. Thus the abscess is to be repeatedly punctured in succession, and the wounds as regularly closed by the first lancet, by which method irritation and suppuration of the cyst will not be induced, the cyst in the cyst will never be allowed to become diseased, and it will be rendered smaller and smaller, till the cure is complete.

In a few instances, the worst case, perhaps, is to be made to preserve or finish the repeated punctures which it may be necessary to make; but still according to our view, the cyst is a solid body, and sufficient opportunity to connect so much, that to seal the wound may be of alarming extent. It is also a fact, that the cyst does not invariably become more indurated and less suppurative after the treatment here been once or twice practiced in the above way. He disposition to absorb lumbar abscesses.

The knowledge of the fact, that the cysts of all abscesses are the same, should lead us to see as frequent other means, which Mr. Abernethy employs, as likely to promote the dispersion of the abscess, by quickening the action of the abscess. It is not kept open with saline issues, but, especially, sometimes roasts of the subject of pus, as the matter will coagulate in this object. When the vertebrae are injured, there are likely to be cured.

In the rapid consolidation the tumor always occurs. If an opening is made in the abscess, the cyst is at first more likely to be irritated than when the tumor are not diseased, and the surface of the cyst is rendered much less likely to undergo any improvement, in consequence of the very formation of an organized exudation. The same will effect of local suppuration, to which case, the absorption of abscess here is always retarded by the presence of organized matter and case, which feed down to the bone.

Mr. Abernethy succeeded in curing some lumbar abscesses without opening them. Large incisions applied to the integuments covering the abscess, and kept open with the abscess lancet, effected the cure. When the punctures produced great collection of matter, he used a small lance, which he introduced in the same place as often as necessary. He observed that the patient was not allowed to rest in any other way, but to keep after using a small lance. I cannot, however, discover any reason, for his practice in relation to the abscess here, except that he was obliged

malaise, nervousness, fever, and malaise. The inflammation of the breast sometimes assumes a suppurative character, sometimes they are only met in particular places. The inflammation may affect the mammary gland itself, or be limited to the skin and surrounding cellular substance. In the latter case, the inflamed part is equally acute, but when the glandular structure of the breast is also affected, the enlargement is irregular, and seems to consist of two or more large tumours, situated in the substance of the part. The pain often extends to the axillary glands. The secretion of the milk is not always suppressed, when the inflammation is limited to the (epithelium), and any portion is said to pass on more quickly than in the affection of the mammary gland itself. When the symptoms of inflammation continue to increase for two or three days, suppuration may be expected; unless the progress of the inflammation be slow, and the degree moderate, in which circumstances suppuration may often be avoided, even as late as a fortnight after the first attack. When inflammation of the breast is generally attended with more or less epigastric pain, anorexia, &c.—(See Form.) According to the valuable description lately given of disease by Sir Ashley Cooper, it is observed in the first stage, suppurative in the second, and abscessive in the third. Swelling is followed by a loss of inflammation upon the surface of the breast, and discharging very "pale" milk. "A particular phenomenon and sometimes an observed at the part of the breast, with a sense of fluctuation beneath the power of matter. The constitution also highly excited, which is excited by the violence of the swelling, accompanied by heat and profuse perspiration. Over the most prominent part of the swelling, the cellular sequences, dermides follows in the case, and the matter becomes disengaged through the aperture thus produced."—(Illustrations of Diseases of the Breast, p. 2.)

When suppuration takes in mammary abscesses, within the first three months after parturition; but they may also reach beyond the disorder or long as they continue to work.

The most common cause of mammary abscess, as accounted by writers in general, are, rejecting the secretion of milk at an early period; mental disturbance, fright, &c. exposure to cold; moving the arms too much while the breasts are large and engorged; bruise, and other external injuries. The causes are all of a suppurative kind. In Sir Ashley Cooper's opinion, the principal cause of acute inflammation and suppuration of the breast, is "the rush of blood, which flows freely such time the child is applied to the breast, and which by nature is called the discharge, and is the preparatory step to the secretion of milk." He also refers to the frequent exposure of the breasts by sitting, and the active exertions of the child in suckling, as promoting the origin of the complaint. This view, he says, often produces these abscesses immediately after the giving on, by not putting the child soon enough to the breast, and by giving them other strong stimuli.—(See Illustrations of Diseases of the Breast, p. 2.)

The matter is sometimes contained in one cyst or cavity; sometimes in several; but the abscess generally breaks into the nipple.

As the inflammation of the mammae are attended with considerable suppuration, there they should be carefully distinguished from what we call a milk abscess.—(See Form.) It is said that sometimes the pressure of the mamma, which have existed a long while, often diminishes when the discharge of a milk abscess. Women who have been long pregnant are sometimes affected with suppuration in the breast, supposed by Sir James to be connected with abortion or miscarriage shortly after they are able to discharge the breast.

In the early period of the affection, suppuration should be attempted. The following are the principal means for this purpose:—(See Form.) The first, is to keep the inflamed breast from being disturbed; resting the arm in a sling; sometimes keeping the milk tenderly rubbed out of proper intervals;—careless application, consisting spirit of wine or liniment of the discharge of effluvia. "If the patient suffers from the cold produced by the evacuation of the milk, a flannel fold pressed may be substituted for it, occasionally applying leeches, and still no effecting that the blood depends

upon temper purging."—(See Dr. Cooper's Illustrations of Diseases of the Breast, p. 3.)

When matter cannot be prevented from forming, an incision is made in a good application, or the surgeon may apply "incisions of paper, lint, and poultices made with milk and sweet almond oil, mixed with brandy," which last should be renewed three or four times a day. In order to lessen the patient's suffering, Sir Ashley Cooper recommends opium combined with the sugar of marsh-mallows, or simple milk dragees with small doses of sulphate of magnesia. In general the abscess should be opened or broken of itself, unless it should be either of a chronic nature in which case it may be opened in a dependent part with a lancet. Much difference of opinion prevails respecting the practice of opening abscesses of the breast.—I consider Sir Ashley Cooper's directions extremely sensible. "If (says he) the abscess be quick in the progress, if it be placed on the anterior surface of the breast, and if the suppuration which it contains, are not extensively spread, it is best to leave it in its natural state. But if, on the contrary, the abscess, by its communication, be very deeply placed, if its progress be tedious, if the local sufferings be extremely severe, if there be a high degree of sensitive fever, and the patient suffer from profuse perspiration and want of rest, much may be cured, and pain avoided, by discharging the matter with a lancet."—(See Illustrations of Diseases of the Breast, p. 20.) The same experienced surgeon disapproves, however, of introducing the lancet through a dense covering of the abscess, as the opening will not procure a free discharge of the matter, but will heal by adhesion, after which the accumulation of matter will continue. The opening, he says, should be made where the matter is most superficial, and the fluctuation is strongest, and its size should be in proportion to its depth. Scarses sometimes form, and not yet heal, and freely spread with a driblet and mixed honey. When the cavity of the abscess began to be filled up with granulations, the position may be cut off, and a perfect dressing applied.

For stopping the considerable suppuration, which sometimes contains a long white matter the abscess is cured, the most effectual plans are those with concentrated acetic acid, the iodine tincture, or the strong liniment with 1) of the first iodine in each ounce of oil, and the occasional exhibition of purgative medicines, with leeches, in the suppurated callosity, according to the state of the constitution.

If the abscess be small, Sir Ashley Cooper allows the patient suck the affected breast as well as the other; but if much of the mamma be involved in the disease, he lets the infant suck the other breast, and directs the mother to draw the other herself by means of the glass tube described in the purpose. When the child is prevented from suckling by excruciating or violent pain of the nipple, the milk secretaries are large, greatly, and inflammation is excited. Here Sir Ashley also recommends the breast to be drawn; but he thinks, that otherwise the child can be nursed to it the better. He gives a solution of a drachm of borax in three ounces and a half of water, and puts an ounce of spirit of wine, the best application for a sore nipple. Many practitioners use diluted laudanum, tincture of zinc, or wine, or that of calomel and lime-water. Sir Ashley feels that arguments do not precisely agree with the part; but if used, he prefers that of laudanum, or wine, or simple water.

Sometimes, when the swelling is excited, a considerable quantity of milk is discharged, in this case, Sir Ashley recommends a sponge (not to be introduced into the parol, by which means the adhesive inflammation and obliteration of the cavity will be produced).—(See Form, vol. 2, p. 485.)

Mr. Bay describes a very complicated abscess of the breast out of five distinct abscesses, and not confined to prevent her suckling manner. Its situation renders all superficial applications inefficient. The inflammation stage is tedious, and when the matter has matured it is only towards the discharge continues, and there was tendency to healing. Sometimes the matter lodged behind the nipple, as well as in the substance of the gland, and broke out in different places, the intermediate parts of the breast being so affected with a serous infiltration. Numerous abscesses ran in different directions, and, when opened, a soft purple fungus exposed its matter. The disease went on in

one-sixth or one-eighth of the whole, a proportion, however, much greater than what had been at first supposed. But, from a fear that the several single parts harmful to the system, by the cold property which they denoted it to possess, and that it might become watery, rheumatic, or puerile, they combined with it a mixture of ingredients of a warm aromatic nature, or supposed it potent with; for example, oil of cinnamon, nutmeg, cloves, almonds, the sweet oil of lavender, rosemary, and a thousand other substances, which were incorporated with the cathartic. The members, joints, and the whole of the body, except the head, belly, and chest, were rubbed with this composition, and the frictions were repeated at variable intervals, until the strongest signs of inflammation appeared.

The ingredients of the plasters resembled those of the cathartics, only they contained less fat, for which was substituted a sufficient quantity of wax, to give them a proper consistence. This composition was applied to the arms, and the whole body was covered with it, excepting the parts in which it was not liable to putrefaction. The plasters were kept on till inflammation began.

The frictions were made with quicksilver, intermitted while the patient is asleep, or else with creosote. These substances were mixed with tany or resinous bases, such as styrac, rosin, &c., and all the ingredients being reduced to powder, were made into a paste with a sufficient quantity of turpentine or resinous substances. The salve was then placed in a tin, and used on purpose, or under a little kind of heat, and of which the head was generally allowed to partake. A cooling diet, consisting of barley water, was given both before and after the use of these frictions. The patient was left exposed to the frictions, which were made to continue in a profuse perspiration, which they took great pains to keep up and increase, by putting him into a warm bed, washing him with boiling, for about two hours, after which he was rubbed quickly and given some food. The plan was pursued in every day, till a salivation was produced, which was kept up as long as necessary. The method of treatment is described by Astruc, and particularly perspiration, and afterwards for the purpose, hereafter more recommended by Lacombe at Paris, and more recently, by Abernethy in England.

Of the three methods which have just been described, only the first is at present generally in use, and lymphitis is consequently absent. It was found, not only that mercurial phlegms caused heat, redness, itching, and disagreeable eruptions, but that the method was extremely slow and uncertain. Hence, plasters are now only used in tropical climates.

Purges, considered as the only means of curing inflammation, however, although they form a method of applying mercury in a very ancient manner, they are, as already managed, liable to several objections. In this way, it was quite impossible to regulate the quantity of mercury used, which varied according to the greater or less activity of the liver, the pulse of the patient, and other circumstances. The effect of the purge on the organs of respiration also frequently proved very oppressive; and mercury, applied in the way of frictions, might frequently occasion mercurial "pains," &c., that in any other manner. In Mr. Astruc's example, however, frictions, in order to cure inflammation, let only produce it, but the very best way of affecting the constitution.

Frictions with mercury have always been regarded as the best method. They have undergone many diverse changes and by being rendered more specific, have been greatly improved. All the warm aromatic ingredients have been eliminated from the ointment, not only as useless, but as useless and injurious to the skin. It remains now, the question of mercury in the fat has also been very much improved.

METHOD EMPLOYED IN THE ADMINISTRATION OF MERCURY, FOR SCURVILLOUS CONSTITUTIONS, &c.

When entered in the preparation of the medicine, and the nature of applying it, are to be considered, the first thing, the preparation and mode should consist in the best possible, or improvement of the patient; and, secondly, the preparation and mode of administering it, that best remedy conveys the necessary quantity into the constitution. Mercury is carried into the constitution

in the same way as other substances, either by being absorbed from the surface of the body, or from the alimentary canal. It cannot, however, at all times, be taken into the constitution in both ways; notwithstanding the absorption of the skin will not readily receive it, at least, no effect is produced, either on the disease or constitution, from this mode of application. In this circumstance, mercury must be given by the mouth, although the plan may be very improper in itself, in speech, and often inconvenient. On the other hand, the external frictions sometimes will not take up the medicine, or, at least, no effect is produced on the disease, or the constitution.

In such cases, all the different preparations of the medicine should be tried; for sometimes one succeeds which another will not. In some cases, mercury seems to have no effect, either applied externally, or taken into the stomach. Many persons seem to absorb mercury better than others; such are probably all internal surfaces and lungs. Thirty grains of calomel rubbed upon the skin, have not more effect than three or five taken by the mouth. Drawing small doses with the purgative sometimes causes a salivation.—(See *History of the Venereal Disease*, p. 325, 326.)

Before the propriety of putting the mercury into the constitution is solved, it is proper to consider the extent of the patient, each mode having its convenience and disadvantages, depending on the nature of the parts to which it is applied, or on certain situations of life at the time. Hence, it should be given in the way most suitable to each circumstance.

In many, the benefit can hardly be ascertained at all, and it should then be given in the richest form possible, commencing with such medicines as will best be correct in violent local effects, although not so specific as the calomel.

When mercury can be thrown into the constitution with propriety by the external method, it is preferable in the external plan, because the skin is not easily so sensitive to the action of mercury, and therefore is capable of being rubbed with more than the stomach. The constitution is also less injured. Many persons in mercury would not feel the effect, if the medicine were only given internally, because it proves painful to the stomach and bowels, which given in any form, is joined with the greatest corrosion. Every one, however, has not opportunities of rubbing in mercury, and it therefore obliged, if possible, to take it by the mouth.—(See *History*, p. 325.)

Mercury has two effects, one as a diaphoretic on the constitution and particular parts; the other as a specific against a diseased action of the whole body, or of parts. The latter action can only be ascertained by the disease disappearing.

When mercury is given, in venereal cases, the first attention should be to the quantity, and in right effects in a given time, which is then brought to a proper pitch, and only to be kept up, and the decline of the disease to be watched, so by this we judge of the variable osseous effects of the medicine, and when great variation is observably seen, be necessary. The whole effects of mercury affect either the whole constitution, or some parts capable of secretion. In the first, it produces universal morbidity, making it more susceptible of all impressions. It quickens the pulse, increases its frequency, and occasions a kind of comparative fever. In some constitutions, it operates like a poison; while in others, it produces a kind of local fever, that is, a small quick pulse, loss of appetite, restlessness, when of sleep, and a warm complexion, with a number of venereal eruptions, and such effects necessarily diminish on the patient becoming a little accustomed to the medicine. Mercury also produces a poisonous form of the constitution, and makes of a venereal nature.—(See *History*, p. 325, 326.)

The quantity of mercury to be thrown into the constitution for the cure of any venereal complaint, must be proportioned to the violence of the disease. However, we are not guided by two circumstances, namely, the time in which any given quantity is to be thrown in, and the effects of it on some parts of the body, as the salivary glands, skin, or intestines. For mercury may be thrown into the same constitution in very different quantities, or as to produce the same salivary effect, but the two very different quantities may be in different days, for instance, one ounce of mercurial ointment, used in two days will have more

make the sensation experienced from the application of nitrate. The body is passively convulsed, but action is often protracted by very slight causes.

On the first or second day, an eruption usually commences about dusk, the colour of which is either dark or bright red; the papule are at first thickened elevated, resembling very small blisters in texture. Sometimes, but rarely, the eruption appears like articularia, and in such instances the disease is observed to be very mild. The papule very speedily run together, so that it is not unusual to find a confluent eruption, which disappears in process. In most cases, it begins first on the wrists, inside of the thighs, forearm, or where pressure has been applied, and the circumference of the face affected becomes much swollen. There also show themselves freckles, which are tinged with a purplish tinge, and unaccompanied by papule. This effusion itself suddenly over the entire body. Thus, however, may be considered an exception. In every instance which came under my observation, it was confined at first to a few places, and then these gradually extended, until the distended portion of the eruption had gained, and the papule were also raised. But in those cases which resembled articularia, a number of small, vesicles, which contain a straw-coloured fluid, form the commencement, interspersed among the papule. Contrary to what happens in most diseases accompanied with cutaneous affections, the febrile symptoms are much aggravated, and continue to increase after the eruption has been completed. The pulse in general beats from 120 to 140 in a minute, the third cordages are rigid, and the pupils extremely unequal, seldom enjoys quiet sleep. When the eruption has continued in this manner for a certain period, the circle begins to peel off in thin, white, scaly exfoliation, and whilst these are observed in solution. This desquamation has not been attended to by Dr. Harrison or Mr. Alcock, by giving the same name to the desquamation which occurs in the last stage, confining both together. It is common to these places where the eruption first made its appearance, and in this order spreads to other parts. About this period the face becomes much more swollen, and the eyes acquire a somewhat inflamed.

The eruption of this stage is very violent; sometimes it continues from ten to fourteen days, and in other cases it terminates in half that time. When the disease has appeared in its mildest form, the patient recovers immediately after the desquamation, a new circle having formed underneath; but, if severe, he has only experienced the milder part of his sufferings, and the skin now assumes a new appearance, which I have considered as the second stage.

The skin at this period appears as if studded with innumerable minute vesicles, which are filled with a purplish fluid. These vesicles may be expected, at the patient, at the close of the first stage, a complete loss of sensation, and some of burning heat, in those parts from which the cutaneous exfoliation have fallen. This fever sometimes for a day or two, but are more commonly less, immediately after their formation, by the patient suffering there, in order to relieve the from disease afflicts such which these parts are affected. They terminate a series, sometimes mild, which possesses with a very desquamation which is to induce issues in the patient himself, and thus what appears near his bedside. The skin is so tender that it may easily be torn by any person who touches or examines it.

This skin is peeled off most especially from the wrists, front, inside of the thighs, or whenever the skin forms folds, and the underlying glands are most numerous. The entire discharge from these glands would be fatal, with the vessels, an inflammation, which may be considered as the third or last stage.

These eruptions are generally very large, and, when detached, leave the form of the parts from which they have fallen. Their colour is yellowish, but sometimes appears dark and dirty. This period of the disease might be termed, I think, with much propriety, the stage of desquamation, because it is distinguished by the fact from the desquamation, which has been already noticed. From the use of the last two stages I have observed that who have described the disease have mistaken it for the desquamation of a degree of erysipelas which has caused by pressure on the skin, and not by disease. When the stage appears, the face becomes

more affected, the eyes intolerant of light, and the feet swollen, inflamed, and sometimes inverted. The crusts formed on the face, as in other parts of the body, before falling off, divide number, so as to leave cracks and fissures, which produce a hideous expression of countenance; and the eruptions are also, from the general swelling of the face, completely closed. The back and hairy scalp are best affected, and, even in very severe cases, these parts are sometimes observed to escape entirely. The patient, while in this state, is exempted to almost from every kind of motion, on account of the pain which he experiences on the slightest exertion, and which he describes as if his flesh were cracking. The crusts also fall off in such abundance, that the bed appears as if covered with the same of foam. While the eruption is only making its appearance in one place, another part may have arrived at its most advanced stage, so that at the different stages of the disease may be present at one time in the same individual. It is attended with typhus through its entire course, but is very anxious to observe, that the appetite for food is more common, freer than in typhus, and sometimes is even voracious. This voraciousness was particularly remarkable in a patient who laboured under the disease, in its worst form, for the sake of some morsels, in the Royal Infirmary of Edinburgh; for beside the most horrid glowers of food was voracious sufficient to satisfy his hunger. When the cutaneous eruptions have continued during the progress of the complaint, they do at the advanced period pathologically agreeable; the anxiety and pain of the breast are also very severe, attended in its rough, and bloody expectoration, and the patient always looks emaciated and dejected. The pulse becomes frequent, jerky, and irregular, the tongue black and purplish, and of large diameter, constant, continuous, passing over the surface of the body, and death supervening. In its mild form it only passes through the last stage, and terminates, in a large already named, in a few days, by a slight desquamation. But when severe, it is often protracted more than two months, every stage of the eruption continuing perpetually longer, and when, in this manner, it has run its course, it suddenly breaks out on the face surface and passes through its later stages. (Dr. M'Callan in *Edinb. Med. and Surg. Journal*, No. 5.)

The worse state is the employment of mercury. Dr. M'Callan is inclined to believe what Dr. Gregory, that the application of gold to the body while under the action of mercury, is absolutely necessary for its production; an opinion strengthened by the constant prevalence of cutaneous symptoms. However, Mr. Pearson thought that such his no concern in bringing on the complaint in patients under the influence of mercury. At the same time it seems particularly fortunate, that the disease is not exclusively occasioned by mercury, either in its general or more partial attacks; it has been observed to follow exposure to cold, and to occur in the same individual at regular intervals, without any obvious or adequate cause. (Ratnes's *Synopsis*, p. 226, ed. 2. Rather in *Edinb. Med. and Surg. Journal*, vol. 5, p. 140; *Mercur. in Med. Chir. Trans.* vol. 2, art. 9.)

In the early stage, Mr. Pearson recommends small doses of arsenical powder, with either diaphoretics, or the animalia nervosa. A gentle purgative should be given every three or four days, and opium is peculiar sleep. The little vesicular eruptions does not peel when piled with calomel, or Hoffman's anodyne liquor. Symptomatic and both may be given when the feelings are no longer intense, and the complexion has subsided. Various acid has seemed to give relief. The diet may be light and nutritive, without fermented liquors, however, till the desquamation has almost been effected. Prepared out of the water bath, and often changing the patient's diet, and even when such become still and sleep with the discharge, of all such benefit. If the remedy may stand to wait, Mr. Pearson advises washing the body very freely with warm water; he also covers the parts from which the crusts are detached, with a moist cloth, and covers the appearance before a dry. (P. 128.)

Dr. M'Callan advises the immediate desquamation of mercury; the removal of the patient from warmth, where the animal is in one's society and disposition; but, on account of the very sensible state of the humors, no such precautions are hardly necessary. See the

and back part of the eyelids, it would have been difficult to have treated them altogether by local applications.

PREPARATIONS FOR INTERNAL CURE.

When it is wished to excite a salivary gland, and muscular contractility will not produce the effect, mercury is employed, and when frictions are not convenient or agreeable, the hydragryne syzygium or lotion is often resorted to. The concentration is again, which may be increased to two, a day. It excels, however, in contrast with the viscosity and heaviness of many patients; an inconstitute sometimes obtained by combining the preparation with opium.

As puerile the hydragryne can excite is rarely or never prescribed for the cure of the venereal disease. But it is frequently prescribed as a mild alternative for children, is shown of from gr. v. to gr. a. twice a day, combined with any vaginal cathartic.

The advantage of mercury (especially salivary) was a medicine highly prized for its emphysema virtues by the celebrated Van Swieten, and indeed there is no doubt that the other preparations of mercury are likewise such virtues. It retains most sympathy even now, and probably will always do so. However, like the red oxide, it sometimes destroys the stomach and bowels. Some surgeons are still reluctant to give it the same degree of confidence in respect to its power over syphilis, as they give to mercurial ointments. Mr. Pearson remarks, that "when the medicine is given, to give the primary symptoms of syphilis, it will sometimes succeed, even especially when it produces a considerable degree of swelling of the glands, and the transient specific effect of mercury is the usual symptom. But it is often followed by temporary or a recent change; and when the symptoms have vanished during the administration of mercurial salivary, I have known a more powerful course of that medicine fail to secure the patient from a constitutional affection. The action of any mercurials is then simple mercury, calomel, or salivary mercury preparations, such as to be confined to the rate of primary symptoms may constitute salivary. The latter will often check the progress of secondary symptoms very successfully, and I think it is particularly efficacious in relieving venereal pain, in healing ulcers of the throat, and in promoting the disappearance of eruptions. Yet even in these cases, it never yields a permanent benefit; for new symptoms will appear during the use of it; and on many occasions it will fail of affording the least advantage to the patient from first to last. It is sometimes, indeed, employ this preparation in several cases; but it is either at the beginning of a venereal eruption, to bring the constitution under the influence of mercury at an early period, or during a course of infection, with the intention of spreading the action of simple mercury. I sometimes also prescribe it after the conclusion of a course of frictions, to support the mercurial influence in the body, in order to guard against the danger of a relapse. And on some occasions whenever I think it safe to combine in this preparation chiefly and accordingly, for the cure of any truly venereal eruption."—(Pearson on *Local Mercury*.)

The dose of salivary is a quarter of a grain.

The following is a common mode of ordering it. R. Hydragryne syzygium, gr. i. Aquæ Natri Mucosæ, (q. s.) Muc. Dose twice daily.

The substance of *opium* (calomel) is not very much used by modern surgeons for the cure of the venereal disease. Sometimes, indeed, it is given in cases of gonorrhoea, both with the view of preserving the constitutive from infection, and keeping the bowels regular. It is more extensively given as a purgative and anodyne, and for the cure of surgical diseases requiring the system to be slightly under the influence of mercury. It frequently proves severely purgative, when more than two or three grains are given.

The most simple preparations of mercury have generally been derived from the most internally conducting the venereal disease. The plumbic hydrate is the most simple of the internal remedies, being merely mercury mixed with modifications of acidulous substances. Next in internal action, they compare, next frequently employed for the cure of the infection of the venereal disease, that is, while a chance is the only complaint. They are also very extensively given in all stages of the disease, to induce

critical fluxions in bringing the system under the influence of the specific remedy. Two grains of the mass kept for three days will usually do so. When they purge, opium will sometimes prevent this effect.—(See *Venereal Diseases*.)

Mercury, so employed, both constitutionally, and locally, in numerous marginal cases; for the removal of indirect mercurials, and instructions of the parts; for the relief of gonorrhoea, herpetic diseases, eruptions, hydrops antralis, and, and a multitude of other affections, which need not here be specified.

MERCURIC. (Fragrant, the thick and oily, a mixture.) A few words on this remedy.—(See *Mercury*.) MEYERSON was recommended by Dr. A. Rousset for a particular class of venereal eruptions, in the following terms: "The disease for which I primarily recommend the detection of the mercurial part as a cure, is the venereal node that proceeds from a high degree of the morbidity of the blood. In a thickening of the peritoneum, from other causes, I have seen very great effects than it; and the frequency of venereal eruptions is the result of these morbid parts with which venereal eruptions are affected; though in this last case, excepting with regard to the pain that is occasionally the node, I have not found its effects in certain, as I have found it had given to believe. I do not find it effective in the cure of any other symptoms of the venereal disease."—(Méd. Obs. and Exp. vol. 2, p. 134, 135.) Mr. Pearson, however, asserts unequivocally, that mercurials have not the power of curing the venereal disease in any manner, or under any one. Other, if the government should ever reduce the venereal code, as there will be a necessity for taking mercury in as large quantity, and for as long a time, as if no remedy had been exhibited. Certain found this medicine of use in some venereal affections, but, excepting an eruption of the legs, Mr. Pearson has very seldom found it possessed of medicinal value, either in syphilis, or the sequel of that disease, or in venereal affections.—(Pearson on *Local Mercury*, p. 25-26.)

As the possibility of curing most forms of the venereal disease, not only without mercury, but without any internal medicine whatever, is now well established, it is difficult to know at what degree of importance to attach to observations declaring certain agents of the system and its efficacy or inefficiency in the cure of that disease; because, if it admit of a spontaneous cure, but will not get well when mercury or any other particular medicine is exhibited, we are necessarily obliged to suppose that such medicine is worse than useless.

MOLLUSCÆ. The venereal sign of a trepan.

MOLLUSCÆ OREUM. A morbid softness of the bones, which becomes progressively flexible, in consequence either of the insensible absorption of the phosphorus of bone, from which their natural solidity is derived, or of the matter being directly secreted into their texture. The bones affected become specifically lighter.—(See *Light*, *Moll.* in *See* *Reynolds on Moll.* 2, 3.) Dr. Boeck made some experiments, with the view of ascertaining the proportion of earthy matter in bones affected with mollusca: he obtained a dried vertebra of a woman, whose bones were found soft and flexible after her disease. In one part of the dried bone, he found that the quantity of earthy matter only amounted to one-fifth of its weight, and, in another, only to one-eighth, while the proportion in healthy bones amounted to one-third the weight of their whole weight.—(See *Moll.* *Chir.* *Treatise* and *4.* and *Wilson on the Bones and Joints*, p. 335.) In bones, the bone yield, and become dissolved only by slow degrees, and retain their natural flexibility; but in the present disease, they may be at once bent in any direction, and frequently absorb of being readily divided with a knife. The mollusca system is an exceedingly morbidly diseased, and on a large scale is a disease. It is reported, however, to depend upon disease peculiar to the constitution, and the individuals affected with it have been remarked to be exactly about as much beyond the juvenile period of life (J. Wilson, *loc. cit.* p. 222), and generally, if not always, women.—(See *Wilson on Mollusca* in *See* *Reynolds on Moll.* 2, p. 172. *Practical Cases of Mollusca*, 1, 2, 3, 15.) The system, however, is reported, in which the patient was a young man, numerous years of age.—(Theobaldus, in *See* *Wilson on Moll.* 2, p. 225.) Surgical writers have usually

phlegmatic masses, and early first involution when the cellular membrane and basement, and a considerable of suppuration and mortification is beginning under the skin.

The symptoms of mortification from inflammation take place suddenly, yet gradually as follows.—The pain and sympathetic fever commonly diminish, the feet are affected by a cold, and of a livid colour, being at the same time, more or less of its natural warmth and sensibility. In some places, the system is detached, while in other situations vesicles arise, filled with a clear or turbid fluid. Such is the state in which we apply the term gangrene, and which stage of the disorder has often rapidly advanced to extinction, when the part becomes a cold, black, Alburnous, senseless callosity, called in technical language a clough.

In some cases, however, there is a stage in which gangrene immediately succeeds inflammation, when two or three days may, in some measure, be regarded as stages or periods of the same disease. They pass immediately into one another, so that it is possible to say precisely where the one state ends, and the other one begins. The symptoms of inflammation in these cases do not disappear before those of gangrene come on; but when either is enlarged gradually and almost imperceptibly, or commences, like the other, the colour acquires a dusky tinge, and extends far, like this form, the swelling increases and becomes more dense, and at the simplest stage, the gangrene, particularly where it attacks the extremities, is visible, often from a considerable remission in the system. — (See Thomson's *Lectures on Inflammation*, p. 200.)

It is to be observed, also, that the part of the body which becomes affected with gangrene does not immediately lose its sensibility, for the pain, on the contrary, is often very much aggravated by the approach of this state. The affected part continues to swell, at least in the larger vessels of the feet, but perhaps not the feet; and from the resistance which it meets with in passing through its capillaries, it is not gradually but suddenly. The swelling ceases, and the cellular membrane contracts, to resume, and the action of the affected and impeded vessels is diminished, the part becomes at length incapable of being restored to its former office in the animal economy. It is, therefore, in its earlier stages only, that gangrene is to be considered as an amiable subsiding of life; for these are those, beyond which, if it progresses, becomes impossible. These limits it may not, in every instance, be easy to define; but they give the boundaries between unimpeded gangrene and the ultimate termination of that state in sphacelus. — (Thomson, *op. cit.* p. 207.)

The causes which produce mortification by impeding the return of blood from the part affected, for the most part, operate by making pressure on the trunk or principal branches of a vein. In these instances, there is always an accumulation of blood in the part which for weeks, becomes of a livid colour, tense, and very painful. Such afterward follows ulcer, and the part becomes black, indurated, cold, insensible, erysipelatous, black, and firm. Such are the circumstances which happen in strangulated hernia, in testis, and in a limb in which the veins have been so long pressed by any hard swelling, such as the foot of a flat-winded horse, as to cause mortification.

Other causes operate by preventing the entrance of arterial blood. The application of a ligature to an artery, as practised in several surgical cases, and all external pressure, that closes the artery or arrests its action, in part, obviously depends for its supply of blood, from the effect. Mortification does not, however, always take place when the trunk of an artery is rendered impassable, because nature supplies the means, by supply of blood through collateral channels. For when the disorder does happen, the part gradually first becomes pale, black, and cold, and soon afterward shrinks, loses its sensibility, grows black, and pained.

In some cases, the mortification proceeds not simply from the interruption of the course of the blood through the principal artery or arteries, but its occurrence is promoted by great violence done to the feet, and in particular by the compression and distention of the cellular membrane with effused blood. No doubt all these causes operated in the fatal example of mortification

which followed a fracture of the thigh, attended with laceration of the femoral artery, as related by Mr. A. Cooper. — (See *Lancet*, vol. 1, p. 286.)

It is usually represented by authors, that mortification only proceeds from a more lowering of the compensation of blood and nervous energy to a part. However, it is to be observed, that parts deprived of all connection with the system, by the division or paralytic state of their nerves, do not frequently succumb to this accident. But as their functions are varied as with less vigour, and their vitality is enervated, the same causes which sometimes produce mortification in parts differently circumstanced, may much more readily occasion it in them. Among the causes of the present species of mortification may be mentioned, great debility, extreme old age, a thickening and ossification of the coats of the arteries, and a consequent diminution of their capacity, and of their muscular and elastic power.

A Fracture, the mortification was one of the earliest effects which took notice of this interruption of the arteries of the leg, in persons who had a great accumulation of the feet and toes. — (See *Phil. Trans.* vol. 22, p. 135, and vol. 24, p. 179.) A similar case was attended by Mr. Keckel, of which he has given an account in his *Chirurgisch-physiologische*. The section was afterwards described by Nauck. — (See *Phil. Trans.* vol. 31, p. 426.) Dr. Thomson has given an example of a very complete obstruction of the arteries of the leg, accompanying a distention of the feet and toes. — (See *Inflammation*, p. 337.) Speaking of the same writer, Mr. Haller remarks, "Experience has proved that obstructions of the arteries rarely at least a constant attendant upon every species of gangrene, to which the extension of cold subjects are liable, and I have found the three principal sources of the leg rarely obliterated by calcification, either in one fixed case of this disease. But our knowledge of the power of calcification, in every part of the body, will not allow us to reject the obliteration of the vessels as a sufficient cause of mortification from a deficient supply of blood. It is therefore necessary for us to remember, that the same disease may probably exist in the collateral branches, upon which it has produced similar effects. But if an extent of vessel be completely blocked up by a thrombus, it loses its elasticity and contractile power, so as to be unable to afford any assistance to the propulsion of the blood; and the existence of pain, supplied by vessels in this state, constitutes a strong stimulus against the agency of the arteries in the circulation of the blood. The above observations, on the cause of this species of gangrene, at once expose its inevitable nature, and the state of the blood-vessels renders the danger of amputation very considerable, unless fortunately the disease in the arteries does not extend as far as the ligature is applied." — (See *Halliday on Diseases of the Arteries and Veins*, p. 61.) However, although the vessel is in an artery, it is not certainly to be considered as being in a state not constantly prevent its desirable event. — (See *Cutis in Arterio-Chir. Trans.* vol. 6, p. 183.)

The preceding facts are particularly entitled to attention, because, as we shall presently find, the opinion that the mortification of the foot and toes arose from no obstruction of the arteries was considered by Mr. Fox as decisive of Ischemia.

It is probable, however, that sometimes other causes are concerned. Edouard Hildrey mentions a fatal case of mortification of the feet and toes, where the patient was in the vigour of life, and apparently of good constitution. After death, a circumferential was found surrounding and compressing the inferior vena cava and aorta, near their bifurcation, so as to prevent the free circulation of the blood in the lower extremities. Mortification of the extremities also sometimes constitutes a direct consequence in the progress of distention of the heart. In a case of dropsy of the chest, Mr. A. Cooper has seen a case upon the feet before all were black, without any appearance of clough. — (See *Lancet*, vol. 1, p. 286.)

The mortification arising from Ischemia continues in the same posture, is slowly advancing to debility and the interrupted pressure which parts sustain, and which obstructs the circulation. Scarcely have the feet occasion to see such a variety of examples of this kind of mortification, particularly in cases of fracture, gangrene from disease of the vessels, laceration of the

under their natural. The blood circulated through them, and returned in supplying with nourishment the parts upon which they were distributed."—(P. 321.) I have often seen the truth of the foregoing statement fully illustrated in cases of circulating tumors, by which several ligues of the human artery are exposed. I have seen the branching bronchial artery situated for more than a month, exactly in its whole extent along the side of the arm, by the ravages of syphilis, and periods of phlebotomy, attended with repeated sloughing; and yet the vessel had no share in carrying off the morbid matter.

It is a curious fact, that the blood coagulates in the large arteries which tend to a mortified part. This occurrence takes place in mortification from the slough, and it is the reason why the separation of a mortified limb is seldom followed by hæmorrhage.

The same occurrence also affords an explanatory key, to the appearance of a mortified limb, there is sometimes hæmorrhage from the vessels, although the limb has been made in one, living part. This fact was first satisfactorily pointed out by Petit the surgeon.—(See *Ann. de Chém. et de Médec.* 1792.) "When a gangrenous limb (says this celebrated surgeon) is cut off in the dead part, no hæmorrhage occurs, because the blood is coagulated in that way in the vessels." He adds, "We have several examples of limbs separated, on account of gangrene, in which no hæmorrhage occurred, although the separation was made a considerable way in the living part; because the clot was not confined in these cases to the dead part, but was continued forwards into the living, as far as the inflammatory disposition extended."

According to Dr. Thomson, (and in confirmation of the foregoing statement as recorded by other medical writers, especially Quercus, and St. O'Halloran.) In one of the cases mentioned by the latter gentleman, and in which no hæmorrhage followed the removal of the limb, the ligatures were made over inches above the division of the dead from the living parts. Dr. Thomson has seen a still larger portion of human artery closed up with coagulated blood, after a mortification of the foot and leg; and, in one example, when the mortification began in the thigh, he saw the coagulation of the blood in the external duct, extending up to the origin of this vessel from the aorta. "So copious, indeed, is the coagulation of the blood in the limbs affected with mortification (observes Dr. Thomson), that it has been supposed to be a necessary and essential effect of this disease. This opinion, however, does not appear to be well founded; for I have seen several instances in which a limb was mortified and dropped off, without hæmorrhage having occurred from the vessels divided by nature; and yet, in examining the vessels of the stumps of these patients after death, I have not been able to find any clots, either of coagulated blood, or of coagulable lymph. In the cases in which I believe the adhesive inflammation, proceeding in the line of separation between the dead and living parts, had extended to the blood vessels, and their lower surfaces, being inflamed and pressed together by the swelling which occurs, had adhesion as it so close up their communication. It is in this way we must find that the hæmorrhagic ligature, which is applied to the divided extremities of arteries and veins, and it is this adhesion by the process of adhesion of the extremities of the arteries and veins to the neighbouring parts of the coagulated mass, that is really prevents the recurrence of hæmorrhage when the mortified limbs fall off, or are removed by the knife. The coagulation of the blood in the canal of the vessels may also be sufficient. It may tend, in instances in which it occurs, for a time, to restrain hæmorrhage; but it fully illustrates by its extension to the blood in the substance of the arteries and veins that the recurrence of hæmorrhage can be neither and permanently prevented against. Indeed, to me, it seems doubtful, whether the coagulation of the blood, which takes place in mortified limbs, ever takes place in the canal of the vessel, till its extremity and lower communication have been closed by the coagulated lymph which is exuded during the work of the adhesive inflammation."—(See Thomson's *Lectures on Inflammation*, p. 324.)

If gangrene and sphacelus happen to any extremity, it is usually treated with an escharotic.

—A surgical well known to the surgeon

of experience, and often an indication of the mischief, when external signs are less instructive. The truth of this remark is frequently seen in strangulated hernia.

The gangrene also rather immediately a consideration depends. The patient's countenance suddenly assumes a wild cadaverous look; the pulse becomes small, rapid, and sometimes irregular; and perspiration comes on, and the patient is often affected with vomiting, diarrhoea, and delirium.

As Dr. Thomson observes, the constitutional symptoms "often precede, which partake in individual cases, more or less, of an inflammatory, typhoid, or bilious character. But the degree of these differs, in every particular case, from their almost total absence to the highest degree of intensity. The skin is usually hot and dry at the commencement of the attack; the tongue becomes acuminated, brown and furred; the pulse quickens, and less full and strong, than in inflammation; and the state of the pulse is often attended by fluctuating intermittence, and a considerable degree of subjective tenderness. The fever has, in general, more of the hectic than of the typhoid character; as it is more of the typhoid than of the inflammatory type; a circumstance of great importance in the constitutional treatment of mortification. The fever is progressive, and is often accompanied with great anorexia and restlessness, dependent of spirit, weakness of the limbs, and almost always more or less delirium. In the progress of the disease, cold sweats, delirium, and convulsions sometimes occur; a frequent, unaccompanied with nausea, often comes on, and proves a most distressing symptom to the patient. Frequently this delirium is the forerunner of death, does not pass the common stage, after suffering severe pain, spasms, and delirium. But in some, a fever, in others, a sudden subsidence of the constitutional symptoms takes place, accompanied also with the subsidence of the local affections. The commonest inflammation next, and a red line is formed by the adhesive inflammation in the extreme verge of the living part, the dead part separates, and granulation forms; and when the coagulation has so much to sustain the way it has needed, recovery takes place."—(See Thomson's *Lectures on Inflammation*, p. 324.)

It is an erroneous supposition, that mortification, arising from an external local cause, is more easily stopped and cured than that originating from an internal cause. The local cause is sometimes extremely difficult, or even impracticable to remove; and a sphacelus, which is at first merely local, may afterwards become a general abscess, by the internal debility and disorganization of the system, resulting from the complaint. Hence, it is obvious, that a sphacelus may easily extend beyond the limits of its external local cause. On the other hand, a mortification may be reduced to one of a remote variety local; though it arise at first from constitutional causes. Sphacelus from venereal debility, or from such a state of the system as attacks the struts, typhoid fever, &c. is constantly passing, because these causes are very difficult to remove. It is also a fact, that when venereal causes are considered, it is an unchangeable occurrence, not merely because the suppuration is checked, even of those, but because there are in reality associations to the cure.

Hæmorrhages, which are frequently accompanied with mortification of the cellular membrane, usually extend with great rapidity.—(See Jones's *Lectures on Inflammation*, p. 324.)

Sometimes a mortification spreads so slowly, that it does not occupy much extent in the end of several months, or even a whole year. The case, however, is often still the best in this respect. The danger is never altogether over, until the dead part has completely separated. The removal of putrid matter into the circulation (says Richter) is so injurious, that patients subjected perish from the disease. Now after the mortification has ceased to extend.—(See Richter's *Med. Pract.* 1. 2. p. 727.)

This last circumstance is very worth recollecting upon by all the modern medical surgeons; for the doctrine has never gained ground among English surgeons, who entertain little expectation of the bad effect of the absorption of putrid matter in cases of mortification; and the opinion of Mr. Guthrie may be more correct, that nature performs the check through the nervous system, and sometimes the sloughs.—(See Guthrie's *Principles*, p. 121, and 2.)

ing situation may be external agencies, atmospheric, medicinal, &c. In general, however, was internal, because more agencies than outside; and for this purpose we ought to prefer the most perfect means such as those of Hygieine and Medicine.

Of all the mortifications here recommended for the suppression of inflammation, three are adapted with a characteristic efficacy to the Pterygoid body. It is not that this remedy often stops in a very early and superficial manner, but for the reason of the disease. Being a very powerful body, it is thought to operate by strengthening the system, and thus impeding its every part the necessary power for meeting the progress of mortification. But whatever may be the mode of acting, the advantage for this medicine is, that it ought to be employed in almost all cases of mortification, as seen in the violence of the inflammatory stage, and the loss of appetite.

It was Mr. Southworth, surgeon at Northampton, who made this discovery in the year 1714. After him and Boisson, two surgeons in London, were afterwards confirmed the virtue of this remedy. Mr. Boylen, another English surgeon, also discovered, in the *Philosophical Transactions*, the good effects which he observed by it. In the *Medical Essays of Edinburgh*, Drs. Mead and Hunter published several cases of mortification of the pterygoid. We are then informed, that when the inflammation was interrupted, the separation of the artery was attended, and that as the surface being exposed to air, the separation would progress more quickly. Since this period, physicians in England and elsewhere have employed this very body in the treatment of mortification; and the repeated statements of its efficacy led us to exhibit it in all cases of this nature without discrimination of the varying state of the general health and local disorder in the different stages of the complaint, and without any reliance on its action and nature, which are subject to variety.

We cannot indeed deny that bark has frequently had the best salutary effect in cases of mortification, though sometimes it may probably have had its effect in it effects which were entirely produced by nature. The following observations made by Dr. Thomson are highly worthy of recollection. "In attending to the effects supposed to result from the operation of the external and internal remedies which are daily employed for the cure of mortification, there are two facts, well ascertained, which appear to us to be generally deserving of just regard. The first of these is, that mortification often stops spontaneously without any consideration whatever from treatment; the second that it often begins and continues to spread, or even after it has stopped for a while occasionally, and succeeds to a fatal mortification in spite of the best directed efforts of the healing art."—(*See Lectures on Inflammation*, p. 227.)

It is quite wrong to prescribe bark in every instance, for there are many cases in which it is counter-indicated, in which it does harm, and still in which it is locally beneficial. It is a mistaken notion of its service when the mortification arises from an external cause, and is the only expedient in a healthy, strong constitution. It is especially unnecessary when the inflammation is of the dry sort, and has crossed the point at the same time that the living tissue appears to be in a state of exhaustion without any increased ability. But if disease particularly arises, that the circumstances of each individual case are liable to be considered, and varied, that though bark may be of great assistance, it may also be indicated.

When mortification is complicated with various disorders of the functions of the bowels and stomach, a very frequent case, bark is chiefly beneficial. Here, the indications to remove the state of the stomach and bowels, with cold opening medicine, and especially calomel. When this has been done, if bark should be indicated by any of the circumstances already pointed out, it may be safely administered.

Sometimes mortification is accompanied with a very typhoid kind of fever, which, whether the cause be the consequence of the local mischief, or impairs the exhibition of bark.

However, mortification may be attended with some inflammatory fever, and then the living margin is actively inflamed and painful. This is particularly the case when mortification is the consequence of

pressure upon inflammation, or of an external injury, to a healthy subject. Here bark need scarcely be administered. Still it is wrong to regard this mortification as necessarily limited whatever sympathies is the extent of inflammation. It has already been observed, that the inflammation frequently has less extent in the origin of the disorder, than in a venereal case, which often requires the exhibition of bark. Even when mortification is the pure effect of inflammation, great protection of strength may subsequently arise, and indeed does regularly take place at a certain period of the disease. In this situation is the voice of experience loudly proclaims the utility of bark, though its exhibition would have been at the time of local inflammation. While genuine inflammatory fever and local inflammation are co-existent with mortification, emollient means are undoubtedly useful; but great caution is requisite, since, in cases of local disease, as it is termed, the inflammatory state very soon changes into one in which the great danger is prostration of strength.

When there is some prostration of strength without any symptom of gastric disorder, or of inflammation, at all typical, bark is evidently proper, though without effect above; diaphoretic and nervous medicines being also necessary, opium, wine, camphor, ammonia, brandy, &c.

We even with rare exceptions mortification in which the pain is experienced more than in the past, without the marked appearance of inflammation. Altho' bark is never of much use, and opium has been resorted to as the medicine in which we should principally reside. This subject will be more fully considered presently, when Mr. Pitt's remarks on a possible mortification of the bowels and feet will be introduced.

Early measures of calomel, and then if want be immediately pronounced, these first salutary effect can be prevented by the addition of a few drops of laudanum to each dose, or by employing the sulphate of quinine instead of the common preparations. Bark frequently disagrees with the stomach; in which case, I should say, think ought not to be continued at all; though, in this circumstance, the usual plan has been to give, instead of the decoction, the infusion of the powder finely divided, and mixed with wine, or some aromatic water. Since the sulphate of quinine is likely to prove the most prepared of bark; but further experience with respect to its real efficacy is still needed.

Several years ago I published a critique on the in-discriminate employment of bark in cases of mortification, and my remarks were inserted in the *British Dispensary*, Dr. Mead's *Cyclopedia*. Many of them were introduced into the second edition of this *Medical Dispensary*, printed in 1815—(*See Dispensary*). Since that period, I am happy to find that the first mortification in which bark was prescribed is beginning to subside, and that on this subject some eminent surgeons have of late publicly avowed themselves which entirely coincide with my former statements. "I think," says Dr. Thomson, "I have frequently seen it very useful when administered in cases of mortification, by lessening the amount of the patient, preventing a shock to food, and sometimes in so doing an obdurate diarrhoea. I believe it to be in mortification a medicine completely forgotten in medicine."—(*See Lectures on Inflammation*, p. 563.) By this expression, Professor Thomson does not mean that bark can never be useful in cases of mortification, but only that it has no specific power in checking the disease, as many have erroneously imagined.

Bark (says Boyer) has been considered, by several distinguished English practitioners, as a true specific against gangrene in general, and especially against that which depends upon an internal cause; but subsequent observations to those published in *Lancet* have proved, that it has no power over the inflammatory state of gangrene, and that it only acts as a powerful tonic in stopping the progress of the disorder, and preventing the separation of the mortified part."—(*See Medical Essays*, 1, p. 111, Paris, 1814.) Boyer also particularly alludes to bark being given while inflammation fever prevails; but whenever he prescribes bark in cases of mortification, he seems to neglect the old preparation of a powerful tonic, in preference to the quantity which can be got into the stomach. On this subject, Mr. Gualtero tells us that he has mortified

slightly to be divided with this complaint. The position would be also soft, smooth, and unassuming; the distention should be slowly increased, and rather, it should be symmetrical than tubercular, white, and part of the red distal should always be in order, or nearly so, not to be freely to become at any critical harpness and drawing and another."

Dr. A. Cooper generally recommends a position composed of part tense and muscular, or that made with stable long pressure; but in that case which I attended with him in various positions, and which will be more fully mentioned, as treatment of inflammation, occasionally one of the characters of cold, and residual problems were all used in vain. Indeed, the very nature of the disease leaves little hope of successful good therapeutic applications. All that can be expected from the best of these is some denudation of parts, and from the want of heat an increase of it, with a more rapid extension of the agglutinated particles.

When the legs are to all appearances, perfectly unaffected, and seem as those as to be capable of being easily taken "away," it is in general thought right to remove them. But however long they stay on, if they be violently twisted off, or the parts by which they hang be divided, a very considerable degree of pain will most completely attend both operations, which however had much better be avoided, as Mr. Pott has seen this very pain they produced from a dead limb twisted, and that of the gangrenous kind. If the patient does not feel these parts will certainly drop off, if he lies out of bed can arise from drawing these.

When the disorder is attended with a great deal of irritation, every subsequent practitioner have allowed the efficacy of opium; though it has not always had the same success in other hands, when the constitution is dependent chiefly on constitutional debility. Dr. Keil had observed, that we must be careful not to give the doses, especially of this; and that the benefits that more than this good when the superior effects go so far as to remove debility, and give the appetite, or cause affections of the heart. Sir A. Cooper joins opium with salutarina, or camphor, and at a time which I have attended with him, he also permitted opium, and wine and opium were allowed. As far as I could judge, the remedies which seemed to have the best effect in producing the patient's continuance in bed, the supports of opium, and camphor, with other mild agents.

It is the nature of the complaint. Position, attributes considerable efficacy in it, as has given at the dose of five grains, twice a day, double quantity of wine, every day.

Five surgeons of the present day believe that opium possesses as much power in the preceding cases as Mr. Keil expressed. While Dr. Yessier affirms that opium is much more essential to the attention of practitioners who look to the treatment of inflammation, yet the observation "I would not by any means have you to put the same reliance on its power as I have seen in the mortification of the toes and feet in all people, where opium to have been done by Mr. Pott. From the facts which I have made, and which have been made by others, I cannot after myself to believe that its present stopping this mortal and of mortification are greater than in any other form or variety of the disease. It is obvious, however, from Mr. Pott's account, that his mind was strongly impressed with a very different opinion. The opinion stated which has been formed from the results of a very small number of cases, and is completely contradicted by the available observations of his successor Mr. Keil, with regard to the frequent inefficiency of opium in the treatment of mortification of the toes and feet."—*See Pott's Lectures on Inflammation*, p. 120.

I believe that this method of mortification very rarely attacks both feet. One mortification proceeds in stages as we have seen, however, I attended in the summer of 1822 with Mr. Hughes of Hildesheim, and the gentleman was the subject of the disease was also treated by Mr. Arthur Cooper. Both feet and legs were attacked and gradually mortified, and up to the knees. The patient lived a month after the commencement of the disease. During most of this time the urine was from 100 to 120, and the stomach as little affected, but the patient died generally in an exhausted state.

For dinner until the last two or three days preceding his death. Until the final stage, when was actually dying. Two circumstances were particularly noticed; first, that the disease never extended itself without being preceded by violent pains in the parts about to be destroyed, so that a patient could always be formed determined from the degree of suffering, whether the progress of the disorder should be made, desirable or not. Secondly, that the process of mortification, and its appearance in one leg, were totally different from those exhibited in the other. In the left, the disorder began on the inside of one of the toes, and followed the course described by Pott in this sign, a general distention of the temperature of the foot and leg was the first thing noticed, without any denudation of the skin, or any excruciating heat on the toes. The redness, after subsiding very much, was followed by total loss of sensibility in the parts, and the cessation of the circulation, and every other sign in them; the foot being little more changed in appearance than that of the healthy and healthy.

2. With respect to the external or local treatment of mortification, the first indication appears to be, inasmuch as possible, to effectual means as may have influence, or kept up the disorder, as the consequences of hardness, tenderness, lameness, or swelling, edema, etc.

When an inflammation spreads from inflammation, which will produce in a considerable degree, it is a case that the dead part will only cause secondary inflammation, and that the principal consideration is to prevent the mortification from spreading to the living tissue, by lessening the inflammation present. Hence, under such circumstances, the application of heat with the warmest oil, and the maintenance of a moderate exposure, from the inflamed parts, surrounding the mortified part, must be just as proper as if the inflammation itself did not exist, and were quite out of all consideration.

It has been justly remarked by an eminent man (*Monro*), that the local treatment of mortification (meaning that its proximity of inflammation has been as stated on the constitutional), notwithstanding have been made down to the living parts, is only that stimulating and sympathetic medicines might be applied to them; such as turpentine, the warmer balsams, and sometimes the essential oils. Warm fomentations have been also applied, as being essential to life; but warm always increases action, and should therefore be well adjusted to the case; while, on the other hand, cold dilutes or lessens power, when carried too far, though it lessens action. Medicines are likewise improper, as the patient is already too weak. It is proper to keep the parts cool, and all the applications should be cold. In cases of mortification from inflammation, good effects have also been seen to arise from the topical as well as internal employment of opium.

But it must be acknowledged, that however proper the employment of cold applications may be in principle, in most of mortification attended with certain causes, fomentations and moisten positions are most commonly preferred in practice.

Refrigerant positions, there are several others which have acquired great celebrity as topical applications in cases of mortification. Of this kind are the distillations carbonic, sulphuric, camphor, and the camphor, all-fresh, in air, even on other subjects, they exert heat than any other.

With respect to stimulating and irritant applications such as leeches, spur of wine, blisters, trichs, and aromatic substances, which have been recommended by a vast number of authors, they are usually abandoned by modern practitioners. Though such things are indeed really useful in preventing distant vital substances from becoming putrid, a very little

* Prepared by mixing about 2 1/2 of finely powdered whole cloves with half a pint of the common alcohol.

† Prepared by mixing into the mixture of strong beer as much camphor as will make the mass of suitable consistency.

‡ Prepared by stirring into the infusion of malt as much camphor as will render the substance of a proper thickness, and then adding about a spoonful of yeast.

is immediate contact with immediately dead. This is indicated, but the parts still alive and so situated should experience the same fate as the contiguous ones. In most of the other cases quoted by Dr. Thompson, my experience leads me to prefer violent sequestering operations, some of which are stronger than the cataplasma rubrum, in the state here, forming, however, an earnest position. When the process by which a slough is detached is somewhat improved, I have seen a good isolation of the contact of organs in water but under the most favorable position, along the line of separation, give considerable more, in the same time that it seemed to produce the changes by which the dead parts were absorbed.

In the gangrene produced by venous and weakness, it seems that the tissue is impeded by increased and injurious to be for weeks and months in some position, the mode of treatment is a matter of extreme importance, and frequently upon the difference of life or death to the poor sufferer. This affords nearly but not in such which are but thick covered with vascular fluid. It seems beyond the latter stages of long continued tissue changes, as after typhoid or hectic fever, attended with tedious sequestrations, or even without these fevers, as in puerperal, and in very bad congested breasts. However, as Dr. Thompson observed, there are two forms of disease arising from posture which have not always been sufficiently distinguished. One of these is the preceding sort of elongation, the other is a chafed, excoriated, and ulcerated state of the part.

Sequelae of mortification tends to cause this sort of excoriated state, that is, to induce a white with the patient's excreta. When this is the case, great irritation is produced by every possible action. If the skin be excoriated and broken, the powder of tannic or tannic calamine, should be sprinkled over the part, or it is as advised by Dr. Thompson, those which contain the oil of turpentine. But when the chafed state of the skin is cured, these remedies are to be laid aside, and an excellent, benzoic, camphor, or stimulating poultice used.—(P. 282.) This seems to be the safe state of such irritation, the solution of epinephrine under a constant heated position, as above given, then may offer advantage.

Dr. A. Cooper recommends the application of nuxvomica. Sometimes he uses a mixture of vinegar and camphorated spirit.

But no topical remedy will insure of these cases and, among the chief cause of the disorder be removed. This is to be effected by change of position, and by the action and condition of the affected parts in convenient places under the patient, not directly under the disease itself, but in situations where they will tend to raise the parts affected from the contact of the bed. A constant hollow pillow will often accomplish this important object: but when possible an entire change of posture is to be preferred.

When nuxvomica succeeds in gangrene from pressure, I have given from camphorated spirit applied: but never with decided advantage. A constant camphorated poultice and in very bad cases the topical use of the solution of epinephrine, when the living margin, are the means upon which I place the most reliance, but these have to be supported by general health, without which active medication neither the spiritual of the patient nor the vitality of any dressing will succeed. Dr. Thompson speaks most highly of the fermenting poultice, which I believe to be in these cases an excellent application. He concludes, however, that he has sometimes found it too irritating, and been obliged to substitute the simple camphor, camphor, or turpentine poultice.—(P. 286.)

When mortification arises from cold, exposure of high exposure, application may be avoided, and cold water, if this again is not required.—(See Case 11.)

The local treatment of the mortification of the fingers and toes, as described by Mr. Pitt, has been already mentioned, and it is this in which the observation is made use of greatest practical.

The gangrene observed of the padua, in which square incision are made, was successfully treated by Mr. K. Wood, by applying the hyperphosphoric acid. It is a simple, and broad position made with the same action. As even in the above history, that, they were treated with the hyperphosphoric acid.—(See

Med. Chir. Trans. vol. 7.) Other cases which also ended well have been treated with list applied in camphorated spirit, and covered with a poultice, or, at first, position made with the spirit rubrum, and after the separation of the slough the ulcer was dressed with good wine and solution of bark in equal proportions. Success cases, however, notwithstanding several instances.—(Journal of Hygiene, p. 303.)

Dr. Thompson is of the opinion, that the separation of the parts in all cases. They even advise the patient to be laid down in the sound position in order to facilitate the application of topical operations, and to favor the separation of the supposed anastomotic qualities of these dressings. But with the exception of those in which the gangrenous parts are under an exposure, or others in which the anastomosis which have caused destruction cover a surface of matter and slowly change solution, there is no consequence of dressing inflammation in any other cases than in the extrusion of slough in the second, the third, or fourth, which presents in the active living parts, even when produced by the most severe frostbite. Instead of advantage. Such incisions cannot be performed without producing a great deal of pain, and producing inflammation, which often induces the mortification spread still farther. But in parts which are in a state of exposure anastomosis anastomosis anastomosis is regarded as those which will cause their vitality, all such portions of tissue as is already loose should be removed. By leaving the most vital part of the tissue in a condition, in which any anastomosis be made for the escape of a great deal of plasma discharges, which being evolved might have a bad effect on the neighboring living parts, and the latter are treated to be themselves freed from the effects of the slough.

The two common modes of accelerating with a cutting instrument the separation of the mortified parts, properly to the completion of the process by which nature breaks the connection between them and the living parts, in general ought to be strictly regulated, as cutting anastomosis produces irritation, and exciting the risk of a renewal of the sloughing. As far as experience goes, gangrenous sloughs are the only instance in which it seems useful to remove the sloughs before they are loose, so as to let the typical appearance extend their action without delay in the advanced living surface.—(See Hospital Gangrene.) Part's treatment with respect to the finger and usually or cutting the sloughs and ligaments, in the mortification of the toes and feet, have been already stated.

If the patient perfectly let nature work, without disturbing her, the separation of the mortified from the living parts will soon figure the establishment of the anastomosis and separation of the dead from the living.

But when the whole thickness of a limb is affected with mortification, ought the surgeon to leave things to nature? or ought he to take measures to amputation?

In general, the performance of amputation is inadvisable, and that usually would be to cause anastomosis between the amputated part, but because a great length of time would be required for the completion of the process, and a serviceable stump would rarely be left.

Another important question then arises, should the surgeon amputate the mortification in a second stage? Or ought he to defer the operation until the line of separation begins to form between the dead and living parts?

In the amputation of the toes and feet, in all cases, Dr. A. Cooper forbids amputation whether others be healthy generations or not, and he declares that if the operation be done, mortification of the stump will be the patient's death will certainly follow.

Amputation says a distinguished professor with long regarded as one of the most important operations which could be employed to prevent the extension of gangrene. This practice, however, has not received the sanction of experience: on the contrary, it has been generally found, wherever it has been practiced, in either acute or chronic gangrene, to coincide with the progress of the disease; and in this way to hasten the death of the patient. The parts which were divided in amputation, though in a distance from a spreading gangrene and from the patient, were found

ing, and saved his life, as that is the conclusion of this case of Alexandria he was quite cured.

"After the taking of this, Mr. Lundy resorted to his majority the surgeon, performed as my patient, and in my ambulance established. Following the acquisition of the first of a soldier belonging to the 5th regiment of the first, the leg having sustained a contusion of a gunshot injury. The gangrene was not formed, and evidently ascending itself, yet the effects of the disorder were delayed, and the patient was left to turn to his rest in Alexandria.

"A faint patient, in office in the same regiment, who in the table in the capture of the same town, was conveyed to my ambulance, as noted in the record. It was the third day after the incident. The foot was gangrenous, and the leg was swollen, and I observed the patient with satisfaction. Before symptoms had been observed, I observed in the leg a little above the place of clasp. The whole member of the stump, of a yellowish black color, was already infected with the gangrenous process (as Lundy found it). The operation, however, stopped the progress of the mischief; separation took place in the stump; some clots were detached; the wound seemed a cleaner appearance; and continuation was completed on the fifth second day. The patient stood steadily with a wooden leg, when I caught the hospital staff, which was broken at Cairo, before he arrived in the hospital, and, to my great regret, he was carried off by this disease, after having escaped the former danger.

"After the landing of Alexandria and Jerusalem (see Lundy), several of my colleagues, surgeons of the first class, undertook, in consequence of my advice and the examples of success which I had noticed in them, the operation of limbs which I had noticed, although the operation was not intended, rather than abandon the patient to a death which appeared inevitable. In general, these practitioners operated the same success as I did myself."—(Ann. de Chir. Militaire, t. 2, p. 131-137.)

In Lundy's remarks upon this subject there are some additional facts and arguments in favor of what he advocates to prove, viz. that in cases of mortification of the extremities, if the patient's life be in danger, amputation ought to be performed, although the thought may yet be in a spreading state. I cannot, however, with having stated the particulars already explained; and the reader, desirous of more, need refer to Lundy's own publication. Certainly the facts which he has added are highly important; they tend to substantiate a doctrine and to prove the error of a practice which have been used in facile terms by most of the distinguished surgeons of modern times. The testimony of Mr. Sharp are rendered questionable; and the truth of the positive assertions of Mr. Pott is not a matter to be disputed. The latter, I will venture, who say that he has observed the experienced make of amputation, while a mortification was spreading, but never seen it occur. As we too conclude, that all these cases which Pott alludes to, were seen, flowing from an internal cause? Or are we to suppose, that the operation failed from having been delayed too long? Or must we suppose, that the nature of the lesion could ever have been changed before the eye of Pott and that of Lundy?

It should be remarked, that the practice of amputation, in cases of spreading mortification, has generally had some success for many years past. Yet the origin of mortification has unquestionably been traced to, and has suggested in this country have sustained a devoted life in the study of surgery and Pott. It is curious, however, that M. de Lundy, who was the express purpose of denouncing his description of the early performance of amputation in gas-diffusion, should have selected of only five cases in which the operation is given, namely, gangrene ascending the stump, mortification of the stump, and the stump of the stump. He says he thinks that amputation ought to be performed on the first appearance of the gangrene in order to prevent it from spreading to the limb.—(See Traité de Chir. Militaire, t. 2, p. 138.) It appears from these the year 1830, Mr. A. C. Hamilton published his notice that amputation in cases of spreading gangrene does not succeed.—(See Practical Chir., an. Surgery, p. 72.)

Mr. Lundy, Mr. Lawrence has also successfully per-

formed at the shoulder, and in a spreading mortification of the limb, the subsequent effect of a mortification. "The skin of the mortified limb was greenish and cold; but the muscle not yet developed. The cellular substance descended with it, and with it a discolored adhesive series; its appearance was not quite natural where the weight took place, it was yellowish and ashy. Small effusions of blood were observed here and there in the course of the artery; even as high as the mortified part. No suppuration of blood in any of the arteries even down to the short and short arteries. All the soft parts were discolored, dark red, and dead, and a firm, reddish fluid being on them." This case had the most favorable termination, and it clearly proves, that mortification of gangrene which occurs in a mortified limb from severe local injury, which so rapidly affects a whole limb, and which the trunk is in two forms, must necessarily be exception to the general position, that amputation should never be made before the line of separation is established between the dead and living parts. Mr. Lawrence, however, would not be understood as intending to recommend the practice in all instances of mortification from local injury. He observes, that a patient may come, in an unusual condition, with a comparatively slight accident, so that it may be regarded as the result of a mortification rather than of the local cause. Amputation would be less successful in such circumstances. It is particularly in mortification following very severe injury, in a subject who is healthy, that Mr. Lawrence holds out the operation to be proper.—(See Ann. de Chir. Militaire, t. 2, p. 134.)

He also reports another instance, in which, because the operation occurred, though the mortification was in a spreading state, Lundy was successful in getting rid of the mortification of the limb from external violence. The operation was done, and the patient, who without it would certainly have perished in a few hours, lived a fortnight; after which he had the prospect of recovery, and died, not of gangrene of the stump, but of consequences of a large abscess in the scapula.

Among the experienced surgeons of Lundy's service, I must not omit to mention Mr. Hume, who has repeatedly, under the circumstances above pointed out, without waiting for the line of separation, and (perhaps) although I certainly was not satisfied, successful. I have no reason to suppose that such recommendations by a surgeon from the rule so generally laid down by authors?—(See Military Surgery, p. 343, & 2.)

With regard to the early performance of amputation, when the symptoms of a limb perishes after exposure to cold, I find some difference of opinion between two very high authorities. Thus M. de Lundy observes, "The mortification which comes on after a part has been frozen, advances so rapidly if the limb be exposed to warmth that in the space of twenty-four hours the vitality and sensibility are quite destroyed, and nothing will remain in restoring its sensibility. Thus the speedy performance of amputation is the only means of preservation to be depended upon. In mortification from an internal cause, the case is different."—(See Précis de Chirurgie, t. 2, p. 138, & 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.)

the following observations, which are sustained in a periodical work. All the world knows that counter-irritation is of great use in the treatment of disease, and almost all the world knows that different kinds of counter-irritation produce different effects on the diseased locality. We do not pretend to specify what is the reason of these different effects, strictly because we do not know. But while physicians as Frey and Larrey, and many others of character, speak so highly in favour of the actual cautery, we perhaps are scarcely authorized to say, that the action of the potential cautery can be made so sensible in all cases. We can readily understand how the actual cautery should fail in disease, however good it may be; for, if we ourselves were patients, we should be able to tell that the pain of the application was too severe as our flesh burned; but the objection of the medical man ought to rest on different grounds. We may say, respecting the matter, that an action may be more easily sustained than that of cautery, so that by the more or less relaxation of the blood-vessels, we may create a superficial ischaemia, or a deep suppurative wound. In fact, in all cases where more than a mere irritation of the skin is required, the actual cautery is certainly in the application possessed by more of the other caustics. Of course it would be improper to compare the actual cautery with those, as with any other counter-irritant, which acts by exciting the skin, and not destroying it; if we compare it, therefore, with the caustic tartar emetic, iodo, arsenic, and the caustic, properly applied, we shall find that it possesses greater advantages than they do. The best of these is a long time in destroying the tissue, and it is very uncertain in the quantity of its effect: moreover, whether the effect be produced at all, generally depends on the disposition and knowledge of the patient's attendance, and not on the medical man. Hence it is not likely often to be properly applied. Iodo and arsenic produce but little permanent effect. Their efficacy, therefore, depends on the intensity and duration daily kept up. Indeed, these also, if they are left to the care of the patient, which they almost always are, soon become inert and useless. The different caustics approach to the matter in their properties. Their effect is, in suppurative, rapidly produced, and in suppurative there is formed; but still, to produce their highest effect, a longer time is necessary than the patient can conveniently stay with his patient; so that, as the operation of the remedy is prolonged on time, and thus the value according to the constitution of the patient, the quantity of effect produced can never be calculated upon. It is very difficult, however, to make a mistake. The effect is almost instantaneous, and the response of the hand requires the quantity of action; so that not only is the more the most manageable of counter-irritants that destroy the skin, but, in every medical case before that subversion of operation. Still, let a small part of the efficacy of counter-irritants, the actual cautery is sustained on the ground.—(See *Med. Intelligence*, vol. 3, p. 378; also *Larrey, Recueil de Mémoires de Chirurgie*, Paris, 1821) and particularly Mr. Douglass's *Treatise of the First and*

second qualities, when it was desirable to gain a little time previously to the commencement of the actual cautery.—(See also the *Effets de l'usage de l'iodine* in the *Cure of the Skin*, Paris, p. 105, ed. 25. From what he says, however, he seems to think that the subjects and morbidities which could radically cure the disease, and he described the benefit derived from them purely to their salutary effects on the stomach and constitution, and purely to their agency in the skin of the throat and lungs, as local applications.—(P. 117.) When Mr. Pearson made these observations, the fact which has now been so unequivocally demonstrated in the many hospitals, that nearly, if not all, the cases of disease going under the name of erysipelas, may be cured without mercury, had not undergone the strict and impartial investigations which have of late years been devoted to the subject.—(See particularly, *On the Treatment of Erysipelas*, with an account of several cases of that disease in which a cure was effected without the use of mercury, by T. Ross, in *Medico-Chir. Trans.* vol. 8, p. 345.) If this point be admitted, it fully establishes the question about the disorganizing effects of various kinds of the actually applied caustics to be taken up in a very different light, not thought with a action that can do this with certainty, get worse and worse, if no remedy whatever be applied, so that it cannot finally get well in itself. While these diseases prevail, the treatment of any erysipelas arising from the use of tartaric or any other acid, was entirely referred to some specific effect supposed to be operative in such medicines. But now the question involves several considerations: first, the actual value of the medicine in eradicating the cause of the disease; secondly, the changes which might happen if the complaint were left to itself; and thirdly, the benefit sometimes to be derived from the application produced in the constitutional and particular circumstances, by the disorganizing of activity. The latter material to every disease the name of a specific for the several diseases, either in the name of the only or a completely certain substance, because nature herself would in time being soon cure to a favourable termination; because the cure can be completed by a variety of other substances named in this publication; and lastly, because mercury, though it may be generally the quickest means of cure, is, in particular cases, complicated with such debility and counter-indications, the worst medicine to aggravate the complaint and prevent any progress towards a favourable termination. Here it is enough to know (and Mr. Pearson himself acknowledges the fact) that in the circumstances above specified, tartaric acid is a safer medicine than mercury. The dose is from ten to twenty drops, which are to be mixed with a proper quantity of water.

Tartaric acid has sometimes been employed as the active ingredient in hypodermic for the cure of gonorrhoea, in the proportion of eight or ten drops in four ounces of distilled water.

In case of poison from arsenic acid, the experiments made by Orfila, find that it is considered caloric and prepared with the most fit substances for neutralizing each portion of the acid as it may arrive by combining with the surface of the mucous membrane, &c. They should be given as soon as possible after the arsenic poison has been swallowed, and being taken in at the patient drink copiously of warm water, milk, broth, or some mucilaginous diluting liquid. When from the symptoms there is reason to believe that inflammation exists in the stomach, or when copious and corrosive vomits, salivaginous regurgitation and gastrodynia are indicated.—(Farrar, *on Poisons*, p. 476, vol. 1, ed. 2, Paris, 1825.) In order to detect the presence of arsenic acid, when mixed with wine or other fluids, we are recommended to add a portion of a form a small vessel over a candle into a glass containing a solution of nitrate of silver. The precipitate of nitrate of silver, which is soluble in ammonia, is not in nitric acid, will take place if the poison contains arsenic acid.—(Thomson's *Dispensary*, p. 434, ed. 2.)

By Murray, who engaged himself in investigating the nature of Dr. Comstock's acid or dissolving herbicide, the arsenic acid is the new form of gas was alleged to have the very important quality of neutralizing putrid exhalations. The gas is extracted from carbonic acid by means of sulphuric acid

surface, the hand, forearm almost always, the chest in febrile cases, sometimes the abdomen.

The disease usually affecting the skin, consists of lesions, generally caused from constitutional causes, though sometimes of external causes, which excite or affect only the surface of a limb, without its action in the system, so as to destroy the secondary tissue, and produce an ulcerated surface.

In external lesions of the limb, where the process is extensive, confined, or superficial, as is shown in some cases, in the degree of the ulcer, is the first, the inflammation rapidly extends to the next stage, and the next stage becomes detached. Hence, a collection of matter forms, which may discharge itself by suppuration, and even death result. In the patient with the ulceration of part of the surface of the limb in the neighbourhood of the *Varicella Chloroform*, *Lancet* (172, p. 256).

The disease may occur in other limbs, as well as those of the extremities. It usually has an opportunity of being a source of the trouble, and in the upper and lower parts of the limb, it is usually the first stage, but in the lower part, it is usually the second stage. In some cases, the disease is confined to the surface, and in some cases, it is extensive. In the latter case, it is usually the second stage, and in some cases, it is extensive. In the latter case, it is usually the second stage, and in some cases, it is extensive.

The inflammation in the disease, which is usually the first stage, is usually the first stage, and in some cases, it is extensive. In the latter case, it is usually the second stage, and in some cases, it is extensive. In the latter case, it is usually the second stage, and in some cases, it is extensive.

distance of the separation of the greater part of the original mass, whose place was supplied by it rather than the lateral surface of the cracked same piece as before 1944 fracture. A third [part] of the remaining large schistosity being assumed, the remaining pieces were where not, and found to be the whole body of the thin. It had continued from the upper to at other way. The main part of the mass had become, comparatively small, no connection with the position, and was gradually broken off from the living parts of the bone in their own. A single standing firm and in between the two members of the original time, preserved the length and great distance - extending to the back. Yet still after this is recognized by the new long can, and through your work it could not be known until—*Md.*, 1876, and *Engl.* 1877.]

Wessington was a steamboat, and, after much suffering, returned, with fifteen hands. The greater part of the shipwreck of the time; for the late was so well repaired, that the crew could have afterwards nearly as fully enjoyed the vessel as the *Wessington* (H.).

"We are not to imagine (says Wedgwood), that these impressions happen by chance, experimentally made upon living animals by Tofts, Blamersbach, Nocton, Dossart, and myself, prove that they certainly follow certain laws."

In fact, whenever the mediastinal structure of the lung bones of pygmy shrews is damaged, these bones become affected with necrosis, and any other ways considered to the fallacious of their destruction.

The observations and experiments cited by Wood have also proved, that it is the solid bones which are actually injured, & through the fact that nature has not yet fully developed the powers of regeneration, since experience fully evinces, that, when a part of the skull is removed, either by a wound, by disease, or by the finger, nature always endeavours to repair the deficiency, the edges of the aperture expanding themselves by means of a bony membrane, furnished by the pericranium, the dura mater, and even the brain itself. *Mem. de l'Acad. des Sciences, 1728, p. 419, 412, 413, 414, 415.* But this the physicians are ignorant, as no recorded cases to justify this, ever have been put into that only a small piece, the whole is taken out by the finger, and while the distance of the cranium is very extensive, as if prepared at all in nature. This fact, which is proved by the observations of Sauvage, Fort, Stollberg, &c. is particularly noted by Sir A. Cooper.

When, in a case of *removal*, says Weidmann, a male is taken off either a long or flat hoop it separates at the segmental *Schultz*, because the granulation which can no longer be supported, then becomes a protrusion, and as soon as the short hoop is removed, they become raised in the adjacent ones.

It is therefore assumed that the parent of regression is able to become particularly active in the early period of life, and as a result regresses, and that this happens most often to children in old persons, pregnant women (Bowl's "Phantasy," p. 124), and in unusual, traumatic and violent situations (Cullis-Speyer, *Chlor. Med.*, 1939, p. 10).

[illegible]

When, therefore, the lesson of the *cloud* of a long house is disrupted by a *success* which does not extend to the critical papers, the case is not a reproduction of the *success*.

When, however, we find the tube of any long bone included in a cast of concrete shell, and the extremity of the tube itself, like that of a bone at the natural joint, we may be certain that it has been detached directly from the pericarpium, and that the long shell which contains it is a new production. On the contrary, if the surface of the dead tube be rough, we may infer, that the specimen has taken place between the innermost layers of the test, and those which are rigidified, the latter composing now the concrete shell in which the specimen is included.—*Wardlaw & Brown, London, 1831.*

This last point, concerning the production of the *apocrypha* that is central to the long traditional debate, is adopted by Rühnkorf as the true one, not only in the instance specified by Waddell, but in every other example where the *apocrypha* seem to be included in either, which has the appearance of being a very profitable, and a task well suggested by Trapp, Powell, etc., so to be treated by the library of the peninsula—*See, Waddell, op. cit.* (p. 336, 10, 11).

As in the *W. carolinensis* population studied, the short or ribbon honey bee is not capable of reproduction. (P. 21). Disserting comments are intercalated in this way, as suggested by Aristotle, but this can state that my subject is for it from a different form—(Hilalides *des* *ty*, in 195.)

Weissagen also never witnessed a reproduction of the spore substance, such as it was before its intrusion, round the vesicles. He always found the submerged matter dense and compact, at least for some time after its formation.

It is very seldom, however, that in presence of time the inner surface of the nose becomes cellular, and is lined with a membrane containing vessels. The regeneration of the *nasella* was first observed by Köhler, and afterward by Dr. J. Thomson, in an extensive series of experiments which he made with Dr. Alexander McDonald, and which were published in the latter gentleman's inaugural dissertation in 1880: (*Die Thomson's Arbeiten an Insekten*, p. 20.) Mr. Russell was not aware of the regeneration of the *nasella*, for he states, that after the absorption or removal of the septum, the cavity of the nose soon becomes filled up with granulations which are at length organized into bony matter. Then, he says, the new bone differs from the original one, in being cold instead of hot. Antiseptics, however, are thoroughly applied. Mr. Russell on this point: in the 24th vol. of the *Mon. de l'Œil*, in the history of a man, the whole of whose clavicle came away, without his being deprived of any of the motion of the arm. The death of this patient, which happened shortly afterward, afforded an opportunity of examining how nature had repaired the loss. Another clavicle was found incorporated, which suffered from the original loss in length not so fully, but only in shape, being shorter, and not so round. It was connected with the scapula and sternum just like the original bone.

The power which then reproduces bones is only a modification of that which creates fractures. Indeed, new cancellous, bony bone, and is known by the shape of callus, promote all the phenomena of new bone, ligament and groups in the same way, and may be supported and sustained in its formation by the same means. (See Callus and Fractures.) It is further不可怀疑的, as Wellman remarks, that the power which effects the reproduction of bones, is the same as that which, in the second stage, ossifies and supports new parts. But to what extent appertains the function of reproducing bones?

Many of the maps have used the whole rock as the matrix. (2) *Myosotis*, *Dianthus*, *Moss* & *Labrad.* in flower. 1770, 1771, 1742, 1747. *Feuilles*, *Wm.* in *Dr.* *Pavia*, 1760. *Saville*, *Mariner*, *Alcalá*, 1761, 20, 21. *Spina*, *Guadalupe*, *Mari-*
ueta, *Alcalá*, *Feuilles*, *Wm.* in *Dr.* *Pavia*, 1760, 20, 21.

Huber (*Klein. Physik. d. E.*, p. 552). Cuthbert (*Edinb. Med. J.*, 2, p. 185). Proust (*Mémoires de l'Académie des sciences*, 1789, p. 455). Berzelius (*Mém. sur les élém.*, 257), and many others, have seen a part of the mass reduction taking place from the resistance of the air.

bone; a thing, says Weidmann, which one is also led to believe by the fact, that, when the whole tube of a long bone is affected with necrosis, the epiphyses, which remain sound and unaltered, unite and grow to the new tube, though no periosteum exists in the situation of the union.

He does Weidmann think, that the spectrum of a fractured shaft, of which fragments have separated, as supposing, proves the contrary—(cf. *Journal für Anatomie und Physiologie des Menschen*, Göttingen, 1840, vol. 1, p. 1). This proposition explains a matter, which had taken place by means of a very broad osseous ring, encompassing the ends of the femur, which he has named. The vessel appears in Weidmann to have been the result of reaction, or lameness, with which the young patient, according to Blumensack's history, had been affected, and by which the union of this bone had been frustrated. Yet, says Weidmann, in other examples of united fractures the ends of the bone are so transposed together by the callus, that there does not exist a single point between them where this substance is affected, and the osseous ring itself is considered and filled with it. (In the *Journal für Anatomie und Physiologie des Menschen*, Göttingen, 1840, vol. 1, p. 1, may be found more considerations offered, by Lamé, against the doctrine, that the periosteum is the organ of ossification.)

Pagani records a case, in which the radius of the tibia were regenerated, and he concludes, that the new osseous substance was not formed from the periosteum, which had been destroyed, but from the remaining portion of healthy bone. (See *Observations Pathologiques*, de M. J. Kunt, his observations on fractures of either of the trochanter superior, where nature had attempted to repair the injury by a formation of very bony matter round the elevated part of the bone, and where the new osseous substance was evidently limited by the vessels of the old bone; the periosteum remaining perfectly sound and unchanged. His remarks are all in support of the doctrine which asserts the production of new bone in the spaces of the remaining portion of living bone.—(See *Journal für Anatomie und Physiologie des Menschen*, Göttingen, 1840, vol. 1, p. 1). The concluding opinion of Mr. Lister, on the same point, I have mentioned in another place.—(See *Fractures*.) And Mr. R. E. has very freely expressed his agreement with those authors: "who do not admit, that the periosteum is endowed with such complicated functions as to be able, not only to repair our lesions, but at the same time to accrete osseous matter." The assertion that from the early of the new bone, he also observes, differs from the periosteum in being less dense and resistant.—(See, in *Diagnosis of the Bones*, p. 41, 55.)

That, however, the periosteum is frequently the organ of the reproduction of the bones, is proved by the experiments of Trays, Blumensack, Bismuth, and Krieger, since in those bones where inevitably regenerated, though there was nothing left of the old bone that could furnish the new reproduction, except the periosteum.

If we examine the new bone at different periods of its development, it appears in the earliest state in the form of a reddish fluid, as has been observed by Dufosse, Poirson, Rognet, Hales, Calver, and others. If we also attend to the progressive changes which this fluid undergoes, we cannot but believe that, as in the embryo, an organic and fixed arrangement of parts takes place. Indeed, it would be erroneous to consider such fluid as devoid of organization and its transference is evident. This fluid is gradually as an first appearance, its consistency and quantity increased gradually increase (Trays, p. 41, 40), so that when it first appears in a liquid, it becomes a gelatinous substance, in which are developed, especially at its inner surface and towards its lower part, long fibres which incessantly become more and more numerous. These fibres in a short time form little layers and reefs and extend themselves every where, so that at length all which was fluid disappears, and the new bone is produced. While young, however, it is still spongy and reddish (Trays, p. 41), but soon becomes denser, harder, and more solid, than that was in which it is a substance, and it requires the ordinary cautery to cut the rest of the bone.

The external surface of the new bone, which, during the period of its formation, was irregular and studded with several projections of various sizes, and placed

with apertures of different dimensions, becomes in the course of time smooth and regular, exactly like the surface of the osseous.

The sides or walls of the new bone, which is in the state of capillary thickness, become also gradually denser.—(Trays, p. 41.) When the epiphyses and long bones are affected in its cavity, the new bone is formed shorter the longer than the original. Has shown up of the ends of the bone, the periosteum from the spongy walls, by the side of the affected bone, until it is in other one capable of producing the action of the osseous, the new bone will be shortened, and some changes in its shape and direction. Adding, says Weidmann, the new bone in its early state, from view of consistency, must yield to the efforts of the periosteum.

In shape is not exactly like that of the original bone, the sides flattened, the round angles, depressions and excavations are not observable, and sometimes others are formed.

How abundant is the process by which the osseous, detached from a bone affected with necrosis, has other functions given to them, and are thus rendered capable of performing their functions.—(Trays, p. 41.)

The periosteum, which exists in some in the situation of the old bone, sometimes, during, and even at all times, when the ossification is taking place, having destroyed the healthy structure of a long bone, send the periosteum involved in the old and in bones; but he observed that, the whole of such bone, had disappeared before the 12th day.—(Trays, p. 41.)

The periosteum which thus survives affords to the new bone as it did to the old one; the vessels, which are now in the situation of the old bone, and contain a great quantity of blood, give rise to large apertures in the regenerated bone, nearly every where in its substance and surface.

Dr. Maderius's description exactly agrees with one of Trays and Weidmann, regarding the formation of the new bone by the periosteum, with this difference, however, that he does not describe the osseous substance as becoming spongy, as stated by the authors, but as disappearing. Dr. Maderius remarks, "that the fact and just hyperosteoarthritis, the bone which takes place in the regeneration of the periosteum; this substance appears the highest degree of vascularity, becomes considerably flattened, soft, spongy, and loosely adherent to the bone. It presents substance, also, which is immediately connected with the periosteum, and forms a vascular sheath, in which the appearance of being inflamed by some matter, though it is not its substance, and it is not connected with the periosteum. These changes in the periosteum in the absorption of the old bone, and the formation of the new osseous matter, and the process in the body of the bone which is to be removed, is one lasting I found, the periosteum could not pass, when the only difference was a solid portion of the medulla, the lower this material connection with the neighbouring parts, as it really seemed to be. The newly regenerated periosteum, but which is not truly from the bone, afterwards a layer to cover the latter by absorption," and while this is going in the inner surface presents covered with the new osseous substance, granulations. "In the case of the old bone is removed, new osseous matter is formed in the substance of the granulations, while they increase in size upon the old bone, until the whole part of it is completely absorbed, resulting in the osseous substance of the bone." What remains of the osseous matter after the absorption of the old bone and the formation of the osseous tube which is to replace the removed substance, upon its vascularity and appears as a new osseous substance. "There never had any appearance of ossification, a body, a sufficient time after the formation of the osseous, as necessary to allow the osseous to be at last totally absorbed; but in some persons I had seen very little remaining. During the progress of the disease, the thickness of the osseous substance which covered the original periosteum, but was gradually thinner; the osseous substance, and a substance which the new osseous bone, in which is ultimately formed a periosteum." Dr. Maderius remarks, that the osseous preparations which authorizes the view above mentioned were presented at St. Bartholomew's Hospital.—(See *Diagnosis of the Bones*, p. 41, 55.)

Dr. Maderius, however, fully agrees with the view expressed a preparation which tends to confirm the

this opening and pouring seeds enough, it was enlarged with a small saw, and a pump had worked. The engine was then adjusted. The patient's note showed that the pump worked, and it was then found to be very satisfactory.

[illegible][illegible][illegible]

NEPHROTOMY. (From *nephe*, a kidney; and *tomos*, to cut.) The operation of cutting a stone out of the kidney; a proceeding which, perhaps, has never been actually put in practice. In the *opéris* Libremont de *Histoire de France*, par Moreau, and in the *Phil. Trans.* for 1656, two cases of what is called nephrosis are mentioned; but in other circumstances the successful Father and others in contrail, that the operation afforded is in the last work, recommending more than the light operation for the stone. With respect to the stone in the latter work, the particulars are not detailed enough to prove that an incision was truly made into the kidney. There is no doubt that such long often been extracted from abscesses about the region of the kidney, after being touched with a stone. But were we to cut into one kidney, we destroy almost all its vessels, and the seat of symptoms, by which the enlargement of a stone is felt in the urinary discovered, will always be very different from the point. When a stone, from its size, cannot pass from the kidney, and causes inflammation and suppuration, we divide the capsule, may perhaps incise into the bladder, and extract the calculus. In this case, suppuration is certainly a violent inflammation. Whence proceeds, that it can only be practised in such circumstances, as are threatening a worse; only we have said by Moreau, is better, upon the subject. In such a case, the operation might be performed with any success, if only the spreading of suppuration any other part of the body.—(See *Waller's* case in *Annals*, n. 361, and 4.)

Myopia may sometimes depend on a proximity to the structure and examination of the eye, by reason of which, the quantity of light, which falls on the retina is in an eye of normal formation, above the measure for a myopia, and abnormally produces him from seeing at a distance. We know that in the eye there is a black substance, named the pigmentary layer, and

supposed one of which is to absorb the redundant rays of light, which enter the pupil. A deficiency of it, might perhaps account for a myopia, being fixed with daylight, and seeing best at night.

For an account of myopia, in the sense of sight blindness, see *the Hæmoptoe*.

1

CECEA. (From *ceca* is from.) A swelling arising from the effusion of a serum fluid in the cellular substance of a part; the effusion, when more extensive and accompanied with a general diuturn tendency, retaining the name of *œdema*. An œdematous part is usually cold and of a pale colour; and as it is light or not at all elastic, it is, as it were, expressionless, or, in other words, it retains the same the appearance of the flaccid, also being loaded in pressure. Effusions of this kind are distinguished with constitutional diseases. In many cases, however, they seem to be extraneous local affections, arising from some causes, or only act upon the parts in which the disease is diffused. That we observe that œdematous effusions of the fluid in the lungs, the kidneys and liver when become extensive, and these are frequently affected with *œdema*, in consequence of the extent of blood through the veins being diminished by the pressure of increased fluids, or of effusion, hæmorrhage, &c. Frequent, however, are known to be particularly subject to attacks of the œdema, owing to the presence of the general disease in the blood vessels. Persons who have been confined to bed, with fractured thighs or legs, generally have more or less *œdema* in their feet and ankles on first getting up again; and the effusion in these cases is probably dependent on the blood being in the vessels of the limbs.

In the treatment of *œdema*, great attention must always be paid to the source of the cause, in order to determine whether the disease originates from a mere local or a general constitutional affection. When it depends on the pressure of a tumour on the veins, as we often see happen in cases of aneurisms, the effect cannot be got rid of till the cause is removed; and the anæsthetic swelling must be lessened, before the effusion can be taken off the same beneficial change. When *œdema* is the effect of vascular weakness in a limb, in consequence of sprains, rheumatism, &c. the best means of relief is to support the part affected, with a broad stocking or a flannel roller, while they are also to be rubbed with iodine, and bathed with cold spring water, till they have perfectly recovered their tone.

With regard to the ordinary treatment on the advanced stage of pregnancy, a complete cure cannot be expected till after delivery. The affection is generally more considerable in the afternoon than the morning, owing to the different effects of anæsthetic and a circulatory position. Some relief may be obtained by the patient keeping as much as possible in a horizontal posture; and when great tenderness and pain are on, the parts may be supported with any elastic or spungy application.

Frequently *œdema* is one of the symptoms of suppuration, and when the collection of matter is very deeply situated, sometimes even to the discovery, as is exemplified in cases of erysipelas.

There is a species of *œdema*, accompanied with a degree of heat, pain, &c. in the part, and which, in short, seems combined with purpura. In this case, cold, evaporating issues, the application of leeches, and the exhibition of saline-purgatives are proper. An erysipelous *œdema* is also not weak, in which the treatment should very much resemble what is explained in the article *Erysipelas*.

CEPHALOTOMY. (From *cephala*, the head, and *tomé*, to cut.) The operation of cutting into the meninges, in order to take out of it any foreign body which lodges in it, and can neither be extruded through the nostrils, nor pushed down into the stomach, though the removal is absolutely necessary for the preservation of the patient's life. A fistula, where a canal was lodged

in the upper part of the meninges, usually extrudes the foreign body, but by its pressure upon the brain, produces the most urgent symptoms of suffocation. In this circumstance, if relief cannot be expeditiously afforded in any other manner, and the situation of the foreign body is denoted by a pronounced dilatation of the neck, craniotomy being almost performed without delay. However, when the symptoms are pressing, and accompanied with any possibility of losing the patient's body, either internally or with a post-mortem inspection, the situation of the patient may be, modern surgeons do not sanction the practice. And this difference from the opinion of the first professors of craniotomy, does not arise so much from any reflections upon the greater difficulty of the operation in this circumstance, as from the consideration of its being unlikely to succeed the only purpose which makes its performance at any time proper, viz. that of enabling the surgeon to extract with reasonable certainty the solid body, whose removal, and pressure on the meninges are the immediate cause of the patient's danger. Hence, when the symptoms of suffocation are extremely urgent, but the foreign body produces no external pressure in the neck, the surgeon should in the first instance perform trepanning, so as to remove the anæsthetic pool arising from the suspended state of respiration, and afterwards by such measures for the removal of the solid mass lodged in the meninges, as experience guides him as what likely to prove successful. Though some physicians have cursorily mentioned by Vesalius in his *"Anatomia Chirurgica"*, Goussard, formerly a Dutch physician, surgeon at Ghent, is entitled to the honour of having published the first valuable observations on the subject. (*Mém. de l'Acad. de Chir.* t. 2^o 46.) He states, proved by experiments that the operation might be safely performed upon dogs, which deceased after it very well, and he demonstrated on the dead body that it was equally practicable on the human subject. Nay, what is still more to the point, he brought forward two instances, in which the practice had been successfully adopted on living patients. In May, 1728, Goussard, a surgeon at Ghent, removed, in Linnæus, who called in a vein, in whose meninges a bone was lodged, an inch long and half an inch broad. Various ineffectual attempts were made to force it down into the stomach, and as it was perceptible on the left side of the neck, Goussard ventured to make an incision for its extraction. The bone was thus easily raised out, no bad symptoms followed, and the wound healed up favourably with the aid of a stitching bandage. For six days the patient was not allowed to swallow any kind of food, but ate nourished entirely with cysters. According to Marjard, a similar operation was performed with equal success by Roussé, surgeon-major of the regiment of Mâle. (*Mém. de l'Acad. de Chir.* t. 3.)

Although the best situation of the meninges among the most important parts of the neck, and the meninges, however, an operation of considerable difficulty in the hands even of a skilful surgeon, and one of great danger in those of a less skilful one, in anatomical knowledge, and ignorance of the right way of proceeding, the propriety of performing it, under the circumstances which have been specified, is universally admitted. When, however, I refer to the difficulty and difficulty of the operation, I am assuming a case in which a deliberate discussion is made down to the point of view, without any guidance from the perception of the foreign body within it; a case in which any view of the subject lead me to think, contrarily to those of Goussard, that the experiment would probably be attended with no practical benefit; which is also the sentiment of Baron Boyer. For with respect to ques-

discrepancy between the times of using the instrument. On your second run from this day, I find the time moving (irregularly) recorded in the first two pulses is quite inconsistent in regard to synchronization, but, upon a test on two other days to see the problem with that the pulse was as accurate as published (1000 Hz). And, indeed, my very first exposure was the interestingly interesting problem was a heap of bugs. The use of an oscilloscope has revealed some of it. Surveys exposed, but about the center of spectrum, as well as high, all were treated by error, and there was a distribution of two errors.

Does our university encourage the use of the pro-life, and being disinterested in questioning whether the moral implications that taking place, we should also be interested in knowing that moral, perhaps a little lower than the economic, she finally seemed to reach the conclusion. Although, and still, high are that for a moral, which black, and the same.

[illegible][illegible]

We have discussed testimony to give the foregoing case, as stated in detail, its fullest account of its important provisions, as well as its advantages, and before the agreement which we are to propose, the only thing which could have occurred in this case, it has been the advantage of both parties in all cases where interests are to be secured.

We had various kinds of takes in this case, but must not take them into the situation, though accustomed to put the same into the mixtures. The scene has been mostly at the beginning of the trip (the first in order the (usual) carriage), the carriage of the first by means of the same, and it passed, if made in one, the carriage of the party, and finally, will first among the earlier parties the lower part of the picture, and finally, however, so that it is possible, made through the gate. If finally the other, and being entering the time, the picture, it will be the first to pass through any considerable scene here.

[illegible][illegible]

We are persuaded that this method of lowering moisture of the atmosphere will, in short time, at least, do away the necessity for the expensive fumigation of

meaning a flexible take in the price. At all events, in the case under money, the other could not have been made available, were nothing of the kind, the extra 2 (perhaps, could be joined to the 1000000).

The three most comfortable and very remarkable sales of opiates that we treated the anesthesiologists taking. It was proceeding in much more, it may be proper to state, that we saw our patients about 1 or 2 days, when the was suffering very little discomfort. It is, however, and we really passed our longest period through the situation. So in still more, and we based on these still comfortable, no real report and limit made.

This second case describes a woman exposed in a child's library in this city, who was suffering from skin sores, and the threat encouraged the first (or smallest) problem was subject to pain with considerable stress. After a few months, the problem somewhat better could be passed with having even after a significant

The agenda was called. In this case, by a 19-year-old female (the late Dr. Charles Sefton) who, by the look sharp of the class. In this case, the jobbing seemed to move extremely well. In Dr. Sefton's case, some possible ailments, and last night of the night, and there had the introduction of the class. Also, it may be observed, there was no anxiety for the girls to last night.

Our attention was called to a pair of remarkable examples of the umbrageous in the spring of 1923. Indeed, a moss about thirty years old, one of *Delphinium* make, still now much fragment and discolored from weather. There were no bright parts, but some were seen in the past and which the colored was truly. Indeed, the velvet marks it had a very level skin.

The patient was now reduced to very small quantities of milk, the only article providing nourishment. But he could swallow gradually the small pieces of moist raw steak which he had to digest in his stomach.

We assume that the marginal profit rate for each employer, increased with considerable difficulty, and, indeed, required a degree of force which we did not think fit to apply; that there was no abstention. A few repetitions rendered the possible force very real, and the pattern, already aware of wages, retail, income, and other rates, was able to make the necessary adjustments.

conducted in the postoperative and preoperative periods. The patient (No. 2) was born after cesarean time. At finishing our reproductive every second day, we very gradually changed till we could pass through the pessary (No. 1) with facility. In a few weeks, postoperative was evident; the size of the uterus disappeared; the patient began to take a little thick juice, made by beating ground-up milk; the emaciation was gradually corrected; afterward he could take bread, cooked soft in milk, or other fluids. His health and strength improved rapidly; and two months since he discontinued his care, and returned to a factory a few miles from town.

In a word, then, we are persuaded, that by a patient and careful employment of the powers of nature they will frequently succeed in curing scurvy of the morbidities, even after the disease is far advanced. In the indolent stage of this disease, provided there be nothing specific in the diseased action, we will be sure to succeed.

We have found it odd to believe that this take-out magazine is very little different in demand, content, interpretation, and expression with some localization from wandering or opportunistic in-migrating feral or house cat(s) of fad.

As a participant in the drawings comes to be acknowledged, the difference in *liberal* has an emotional charge, and a slight suggestion of the player's satisfaction to convey a sense of acceptance of the "reformation" of the world and the increased ranking with its grade is indicated. The teacher is about to begin another long, little round that is not a game but that of change is essential time the very is started by a good presentation to be made.

NIL. Be careful about the kind of whiskey is served to the boys in such a case, and choose all pink of the most pure and good, without the strong, stimulating to the nervous system, and to the extreme consequences, in the present critical condition between you, could mean the end of every, should it happen to be the last of the world. There are several ways to be sure of the whiskey, first, use a double strain in the press, and use the purest.

lightly as possible, a river is passed through, so as to make all equally sure.

We need hardly remark, that the index is indispensable in cases of purpura of the conjunctiva.

—Rienj.

OLEUM CAMPHORATUM. R. Oil olive, ℥j. Camphor ʒi. Mix in a suitable vessel. Sometimes employed for promoting the suppuration of inflammation, particularly scrophulous swellings, which are to be rubbed with it once, twice, or three a day according to circumstances.

OLEUM LINI. In surgery, linseed oil is sometimes used as an application to sores, rather than a diluted styrac resin, equally specific of the lippa virus. It has also been applied to cancerous ulcers.

OLEUM MARGANI. The oil of margosa is often used for dissolving gamboge: the formulae are to be rubbed with it two or three times a day.

OLEUM PALMÆ CAMPHORATUM. R. Camphor ʒj. Oil palmæ ℥j. The camphor is to be reduced to powder, and the piece of tallow melted, and infused in bovine plasma cool, so to be mixed with it. A mild topical anæsthetic, sometimes used for promoting salivary excretions, especially those of a scrophulous nature under the jaw.

OLEUM RICINI. In surgical cases regarding the bowels to be covered with the highest degree of anæsthesia possible, the oleum ricini is the best and safest medication. The usual dose is one, two, 1440—spontaneous, which must be repeated every two or three hours, till the desired effect is produced.

OLEUM TERREBINTHINÆ. Oil of turpentine is employed externally as a stimulating liniment, and a styptic. In the acute laryngeal test, by some some, in which respiration is the most active impression. It is sometimes exhibited internally for the cure of glaucoma.

OLEUM TERREBINTHINÆ ATUM. R. Oil turpentine ʒij. Oil podalicæ part. ii. Minc. In glaucoma occasioned by defective or disordered action of the glandular apparatus, Mr. Maule directs a little of this oil to be dropped into the patient's eye, or applied at the end of a small pencil of cotton. When it then becomes taken place, the eye is also, preserved by a small linen, which is placed so close to the eye as to prevent, and kept open with the rustic device. The means sometimes a few days must also be continued every day with a little of each point, added to a poultice.—(See Pharmacop. Classica.)

ONCHALISCELE. (From *Onchal*, the nail, and *Onchal*, a nail.) A rupture or laceration of the nail.—(See *Onchal*.)

ONYCHIA. (From *Onchal*, the nail.) An abscess near the nail of the finger.—(See *Onchal*.)

ONYX. (From *Onchal*, the nail.) A small collection of matter, situated in the anterior chamber of the aqueous humor, and so named from its being shaped like a nail. One of the same nature as *Hyphema*. Matter Juss, Maudslayi, and others, apply to the term onyx, a small abscess between the layers of the cornea.

OPHTHALMIA. (From *Onchal*, the eye.) Ophthalmia, Oculitis, Inflammation of the eye. This is not only a consequence of general affections of fever and adjacent parts, so the exposure of which in consequence depends. It is frequently the primary complaint, and has often the duration of such irreparable, and as far as ever between the period of vision.

After every disease of the eye presents some differences, depending upon the nature of the disease itself, and others arising from the peculiar organization of the patient which happens to be peculiarly affected, the characteristic dissimilarity of ophthalmia, and is subject to a vast number of modifications, according to the particular nature which is induced, and hence, sometimes one species of inflammation, sometimes another, chiefly predominates, while others are less common, and often scarcely distinguishable. Yet, only here, none of the characteristic marks of inflammation are ever entirely absent. This entire appearance the degree of pain is being experienced in a great measure to the touch, including vision of the parts immediately around the inflamed surface of the eye, in the first degree of the inflamed surface, and to the quantity of matter with which each feature and the parts in an immediate vicinity are supplied.

In proof of the truth of this doctrine, he instances when there is internal suppuration, where the pain is very severe, while inflammation of the conjunctiva, the spreading to the deeper texture of the eye, are considered as cases in which the pain is slight, because sensitive inflammation is more and yeting. And without describing every feature suggested by heat to the sensitive elements in the conjunctiva according to the nature which happens to be most affected, I shall briefly add a few other examples quoted by the same author. That the degree of pain, as well as of pain, varies considerably in different states of ophthalmia, is a fact universally known. In the beginning of the inflammation, such ophthalmia is generally less painful than when the inflammation has attained its largest pitch; but it is not equally great in every individual case in every species of ophthalmia, being sometimes more intense and diffused, sometimes less both in degree and extent. This diversity is referred by Boer, and probably with reason, to the texture affected in the eye being furnished with many susceptible blood-vessels, obvious to the sight, and containing vessels more numerous and rather filled with a coarser fluid than with red blood. The looseness or squandering nature of the tissue, it also represents as making a difference in the degree of pain. In inflammation particularly affecting the conjunctiva and sclerotic, says Boer, the ophthalmia is so intense as to give the eye a frightful appearance, as it is not in chronic, where the inflammation of the conjunctiva is more of the nature, the redness is scarcely perceptible, and in the conjunctiva inflammation of the sclerotic, the redness is very faint.—(Lectures on the Ophthalmia, p. 1, p. 34-36.)

Dr. Wren remarks, that the conjunctiva is capable of being stretched to a great extent, owing to the loose structure of the cellular membrane, in which it lies, and consequently little resistance is made to the enlargement of its vessels. From slight irritation they soon become distended with red blood, "but their tone or power of reaction is speedily exhausted, and if the exciting cause is not kept up from increasing slowly they gradually fall into a state of various enlargement, or again contract to the diameter of the vessels." On the other hand, the same experienced writer has pointed out, inflammation of the sclerotic coat is slow in its commencement, and often continues in its progress, even when its origin is violent is point. In the early stage of conjunctival ophthalmia, the inflammation is most observable at a distance from the cornea, around which the membrane often preserves for a length of time its natural appearance. Finally the reverse takes place in the case of sclerotic inflammation, which especially appears at the circumference of the cornea, forming a new vessel or line complete circle, and most conspicuous above it; the first and colour of the vessels being in the stage thus being different from those which appear in the course of conjunctival inflammation. Inflammation of light says Dr. Wren, is usually accompanied with inflammation, and is entirely unaccompanied with that of the conjunctiva.—(On the Diseases of the Eye, p. 11.) If the latter observation be strictly correct, it is to be inferred that in all certain cases of acute ophthalmia, involving the conjunctiva on the front of the eyelid, the sclerotic is more or less affected, as in the beginning of the disorder, than may be said to be in some cases manifestly to every part.

According to Mr. Trenchard, when the sclerotic participates in the inflammation of the conjunctiva, the vessels which pursue a straight course to the margin of the cornea, are strongly distinguished, and being a somewhat darker hue than the arterial vessels upon the same portion of the conjunctiva.—(Synopsis of the Diseases of the Eye, p. 120.)

Described as the pain, redness, swelling, and heat, the few characteristic symptoms of inflammation, may be in cases of ophthalmia, the conjunctiva is more sensitive to the eye, and less subject to excess in such features. Thus, sometimes a considerable itching, the action of the arteries of the eyelid, and eyelid, or of the sclerotic and eyelid eyelid eyelid, and at the Mollusca glands, may be noticed; and sometimes the action of all these parts is more manifested in strikingly stopped. These differences then refer to the latter parts being either themselves inflamed, or sympathizing with the inflammation of the eye. In the first case the action of the muscles

of a light compress, suspended over it from the forehead. Under this treatment, such patients are in five days closed in twenty-four hours, without any suppuration; that the chambers are nearly filled again with aqueous humor, and the intolerance of light, which was only the effect of the loss of this fluid, is entirely removed.

In large deep cut wounds of the eye, whether accidental or made in the extraction of the cataract, the prognosis must be very cautious, and the treatment conducted with the greatest care. As says Beer, if the wound is deep, though the wound is not important in itself, its effects become very serious, and the prognosis highly dangerous to the eye. Hence, when the patient is known to be either an indolent and likely to take proper care of himself, or one who is much alarmed about the fate of his eye, the prognosis should be very guarded, even when the consideration is of the best disposition, because a violent and dangerous attack of ophthalmia is apt to ensue, and destroy the eye sooner than efficient surgery can be performed. For the other hand, when the patient is strong and intelligent, and the case is properly treated, the prognosis is very favorable.

In considerable cuts of the eye, it is easily possible to promote their union with a suitable bandage, and, by efficiently protecting all motion of the eye and eyelids, which is best accomplished when the wound is as well as the injured eye is covered, and the patient kept quiet in bed, until the sides of the wound have grown together.—(See, &c. 1, p. 164.)

All cases of deeply penetrating wounds of the eyelid itself, Beer summarizes the prognosis made in the depression, and relaxation of the eyelid, and in every mode of forming artificial pupils; lacerations of the conjunctiva with cuts of the cornea, lacerations of the eyelids, &c. In these cases, the prognosis, he says, is always very favorable, when the patient can put himself under all the conditions which the treatment requires, and his constitution is good. The first thing here to be carefully fulfilled is, the removal of any fragments of the instrument, or body with which the injury has been inflicted, and it should be recollected, that, in these cases, almost all patients, which are severely discolored, frequently help in the conjunctiva, and, if not immediately treated and removed, produce the very worst consequences. By the weapon being suddenly withdrawn, pieces of the conjunctiva are sometimes torn away, and hang from the eye; Beer directs to be cut off with scissors. The best applications, he says, are either hyaline or antiseptic solutions if taken blood is effused under the conjunctiva, which is applied with a brush. To these cases, he thinks compresses scarcely applicable. When the quantity of blood effused in the loose cellular texture under the conjunctiva is very considerable, he sometimes recommends; but where this practice does not seem likely to answer, and violent erythema collyria are ineffective, some of the ligament should be cut to drain. When any fragments of the instrument have been overlooked, and remain in the part, either a cyclotome, or a pair of forceps, and the fragment is at length detached, or else in a patient of laboring mobility, a soft, spongy, antiseptic dressing, passed externally is found all round the conjunctiva body, and sometimes even projects between the eyelids. Here, according to Beer, the first requisite step is to cut away the ligament with a knife, so as to reach the inflicting fragment under it, and then the rest of the emergency may be removed by touching it with the diatherma, or by the use of a pair of forceps.

When there is lacerated wounds of the cornea, they either penetrate the anterior chamber, or not. They are all of them attended with more or less contusion, laceration, abrasion, and partial rupture of the vitreous anterior lamina of the eyeball; a consideration, as Beer observes, especially affecting the prognosis. When in such injuries of the cornea, inflammation and suppuration cannot be prevented, or the discharge is protracted, an oblique scar is always the consequence, which, when situated in the center of the cornea, is a serious impediment to vision. Every endeavor should therefore be made to unite the wound by the first intention; and the best chance will be afforded by treating the eye precisely in the same manner as after the extraction of the cataract.—(See Cataract.) And when the plan fortuitously succeeds, the

flow of the aqueous humor out of the eye, ceases in about three or four hours, and the aqueous humor becomes diminished again; but the size of the injury continues uniform for some time afterward. The shock, however, ultimately disappears, though much more in young, healthy subjects, than in the aged and feeble. When the opacity does not go off of itself, Beer directs a cyclotome, containing some of the large crystals (see Cataract), and the strong texture of opium, the most efficient means of disposing of it. Through large wounds, penetrating the cornea near its edge, a fold of the iris is apt to protrude, and when it does, it should be replaced, which can easily be effected without injury to the eye by gently rubbing the upper eyelid, and then using a strong light suddenly on the protrusion. In this case, the employment of instruments is considered by Beer highly objectionable. When the iris is not immediately reduced, it is well as the cornea is attached with inflammation, and soon becomes firmly adherent to the edges of the wound.—(See Iris, Protrusion of.)

Large wounds penetrating the eyeball, and making the vitreous humor of a very serious nature, even though the entire part may have received only a prick, or cut, because as the injury has been produced by accident, and not by art, the wound of the iris cannot be free from all laceration and contusion. It is therefore, says Beer, when extensive injuries the iris and tear is healthy individuals of the pupillary and ciliary edges, especially when produced by very sharp instruments, say, it may happen to be in the edge, without any of the consequences, if the contusion is favorable a proof of which fact is seen in the two extreme methods of forming an artificial pupil, viz. the excision of a piece of the iris, and the detachment of the iris from the ciliary ligament, as practiced both by Schmidt and Scarpa. But, according to Beer, an extensive wound, or actual laceration, particularly when it allows the portion of this organ between its two edges, cannot be better even in the best constitutions, and the hemorrhagic consequence is inflammation, soon followed by a partial, or complete closure of the pupil, or exfoliation in the eyeball. When the least amount of injury suffices to injure the iris through the cornea, as a partial tear, and the wound in the latter is extensive, the iris is frequently pulled between the edges of the wound, at the moment when the weapon is withdrawn, and protrudes in a lacerated state. In this case, Beer recommends the iris protruding part of the iris to be cut away with scissors close to the wound in the cornea, when the rest, he says, is generally retained within the eye. Thus, an adhesion of the iris to the cornea, termed synechia anterior, may often be prevented, which, when the lacerated iris is suffered to hang out of the cornea, is inevitable, accompanied by a large opaque cornea.

Some violent blows on the eye, though they cause no wound, are attended with such a contusion of the anterior lamina of the cornea, that more or less of the iris is instantaneously separated from the part of the ciliary ligament where the force is most violent. The consequence of this accident is either a double pupil, or the natural pupil closes, and the artificial one remains open. Both instances may be produced by the lash of a whip, or a horse's tail. In common accident in the narrow street of Vienna, or the threat of any bludgeon weapon against the outer part of the cornea, and they are purposely inflicted in the method of forming an artificial pupil, recommended both by Schmidt and Scarpa.

Wounds which enter the eye through the sclerotics near the cornea, usually produce a considerable effusion of blood in the chambers of the aqueous humor, but Beer thinks, that there is never any necessity for making an opening for its discharge at the lower part of the cornea, except when it is so considerable as completely to hide the iris, at the same time that the eyeball is affected with very painful tension and hardness. In all wounds of the iris it is likewise proper to follow the same treatment as applies to penetrating wounds of the cornea, with this difference, that when the effusion of blood in the chambers of the eye is considerable, the action of the absorbents should be promoted by the immediate employment of viscus rhomatic collyria, and afterward warm spirituous injuncta.

Wounds of the eyeball, affecting the corpus ciliare, are set down by Beer as extremely dangerous, inde-

swelling of the eyeball, where the matter is of an unhealthy quality, and so capable as to make its opening advisable, which, perhaps, however, in a general case, he condemns. The other stated changes, already alluded to, the practitioner must endeavor to remove slowly by proper treatment of the vessel itself.—(*Ibid.*, p. 251.)

Scars's fourth rule in the treatment of the second stage of continuing in general, and of idiopathic inflammation in particular, when the suppurative process is extending itself and threatening to impair the health, is, 3d. To allow the patient such food as is best easy of digestion, and of a very nutritious quality, and even a moderate quantity of wine and spirituous drinks, if he has been accustomed to them. 5th. To direct the patient to keep his eye exposed the greater part of the day, in a fresh air, and if possible add air, and take just exercise enough in various ways to produce a slight degree of fatigue. 6th. When the eye itself is affected with suppuration, and the sight is either already much impaired or quite lost, and, of course, the patient very unhappy and distressed, there consists in being beneficial to let the spirit be supported by society.

The fifth rule or general injunction in the second stage said above by Scars, refers to the necessity, if suppurative inflammation in the suppurative process is attended with a general febrile disturbance. For this purpose, he recommends, 1st. The exhibition of calomel, ipecacuanha, opium, and emetics. 2dly. If they prove ineffectual above, they are to be joined with other means, especially bleed. 3dly. The use of bath, which, in consequence of the sympathy between the skin and eye, is particularly efficacious. 4thly. The injections applied just all from the eye.—(*Ibid.*, p. 257.)

As an appendix to these general remarks, dictated by Scars, on the general treatment of ophthalmia in its first and second stages, I select the substance of some other writers, as either confirming or rendering questionable some of his statements.

According to Scars, when bleeding and other evacuations have been performed, the next most useful measure is the application of a blister to the temple of the neck. He observes, that the skin here and behind the ear has a stronger sympathy with the eye than any other part of the integuments. On the other hand, the late Mr. Ware perceived, in the scrophulous, and says, "When the eyelids have fallen off, and the consequent hemorrhage has ceased, I would advise a blister of the size of half a crown to be applied on the temple, directly over the artery made by the laceration, and I have found, that the sooner the blister was put down the slower, the more efficacious will have proved." He also, that when ophthalmia is very violent, and needs stronger methods, the most beneficial effects are sometimes produced by the application of a blister large enough to cover the whole head.—(*P. 33, 44.*)

With respect to blisters, another modern writer particularly objects to their being applied near the eye, or on the temples, "where they never fail to prove injurious." There is (says he) "but one exception to this as a general rule, in a small case, that blisters applied to the external surface of the eyelids, in cases of purulent ophthalmia, tend considerably to diminish the purulence and viscosity."—(*First of Diseases of the Eye*, p. 17.)

In the second stage of acute ophthalmia, the violent nature of the inflammation of the eye has been very effectively used as a means of cure. In common cases, then, it is more than any to be restrained between the eyelids and globe of the eye twice a day, but in other instances, attended with severe inflammation, once at first will be sufficient. The late Mr. Ware, who brought that disposition into great repute, found that introducing two or three drops of this medicine at the inner canthus, and letting them glide gradually over the eye by gently drawing down the lower eyelid, proved equally beneficial and less painful than letting them fall directly upon the eyeball. Immediately the application is made, it usually produces a copious flow of tears, a swelling, and a sense of heat in the eye; which, notwithstanding, however, soon subsides, and the eye becomes clearer and less distinctly inflamed. But notwithstanding every exaggeration, and almost every opinion is now fully convinced, that the disease cannot be cured by a proper application only when the in-

flammatory action has been previously dissipated by blood-letting, repeated applications, and blisters, and when the action of the vessels has been weakened by the continuance of the disease. Not is any doubt entertained, that the late Mr. Ware went much too far when he recommended the violent nature of opium as a most efficient application in every species and stage of the disease, from the most mild and recent to the most obstinate and inveterate.—(*P. 31.*) Scars has seen the necessity of limiting the use of the remedy in question, and has expressly pointed out, that it is useful only when the violence of the pain and the extension of sight have abated. Indeed Mr. Ware himself, a little before introducing its employment in all cases, has acknowledged, that in certain instances, in which the complaint is generally recent, the eyes appear shining and glossy, and feel exposed to pain on exposure to the light, in which all is retained.—(*P. 34, 35.*) Mr. Travers has remarked, that "there are inflammations, which assume a chronic character at their commencement, gradually progressing, and some of many, of very partial extent, void of pain, and scarcely possessing any signs of inflammation except the congestion of the vessels, or, if any, so feebly marked as to be scarcely or to be disregarded in the treatment. In such cases a single caustic will often restore the healthy action at once. The various nature of opium has acquired a notoriety-like importance from its restraining operation in such cases; a virtue, I believe, not proper to it. A drop or two of the oil or the laudanum, or water impregnated with calomel, or a similar portion of the chronic treatment, or any other stimulant, would do as much."—(*Travers*, &c., p. 22.)

Whenever the patient can easily bear a moderate degree of light, Scars directs all coverings to be removed from the eye, except a shade of green or black silk. A brighter light should be gradually admitted into the chamber every day, so that the eye may become habituated as soon as possible to the open daylight; for, as Scars truly says, nothing has a greater tendency to remove and increase the morbid irritability of the eye, than keeping them unnecessarily long in a dark situation, or covered with compresses and bandages.

Dr. Vetch has seen a distillate to the plan of covering the eye, that he never suffers a shade to be withdrawn, saying that, in suppurative inflammation, it always does a great deal of harm, by preventing a free exposure of the eye to a temperate atmosphere.—(*On Diseases of the Eye*, p. 17.)

Besides the common remedies for inflammation, there are some very powerful means which may be employed for the relief of particular states of ophthalmia with great effect. Thus, as the latter author has observed, by means of hyoscyamus, belladonna, and stramonium (see *Antidotes*), the irritable structure of the eye may be secured from injury, at the same time that other measures are adopted for checking the inflammation. Such medicines may even be applied, in a mechanical form, for detaching any recent adhesion.—(*Op. cit.*, p. 34.)

The use of the anesthetic nuxom is also very extensive: "the slightest application of it in substance (says Dr. Vetch) can often remove the highest degree of morbid sensibility to light, and instantaneously restore quietude to the organ; it can prevent insupportable charges and obscure internal view; and may also be used in solution as a valuable sedative."

The action of it is stimulating and serves a substance in the shade of other having a similar effect say opium, nuxom, but the fact is unquestionable, and well illustrated in the treatment of several diseases.—(*See Green and Ware.*) As medicine used in a more correct sense, it is remarkably that even the weaker forms of moderate laudable irritate, and not more than with moderate opium. The oil of anesthetic by anesthetic preparations is general is very extensive—I have known them (says Mr. Travers) applied to the eyelids, and patients inquire if they might not substitute warm water for the aqueous solution of opium, and solution of poppy and henbane. The same observation applies especially to painful idiopathic sympathetic affections, and acutely irritable ulcers. Upon these a solution of opium often acts as a stimulant and increases pain, while the same morbid action as often ceases it." At the same time, Mr. Travers

lens, which occurs when the inflammation is violent and the eye is disorganized, must be left with the covered state of the cornea. The anterior watery chamber may reach the apical opening of a hemorrhoid, and finally of a tubercular ulcer. The swelling becomes more permanent, and presents a vascular character, either in the middle of the eyelid or close to the outer or inner canthus. The pain is moderate, and of a stinging, burning kind, a throbbing being felt only in the deeper part of the tumor. At length the swelling becomes more and more and less movable at the most projecting point. The secretion from the Meibomian and lachrymal glands, which in the first stage of the disorder, was suppressed, is now again established, but more copiously than in the healthy state. During sleep, a quantity of mucus accumulates between the sides of the eye, and glues them together. An extraordinary sensation of cold and heaviness is felt all about the eye. Ultimately, the most prominent point of the swelling presents a yellowish color, followed by a yellowish firm flap. As the abscess is now completely formed, the fluctuation of matter can be plainly felt.—(Rees, &c. i. p. 269, 36.)

According to the same author, nothing very particular is known respecting the causes of the preceding form of ophthalmic inflammation, and, with the exception of those, he has not been able to discover the proper circumstances which give rise to it.

With regard to the prognosis, if the treatment be neglected or hyaline, the inflammation may gradually become so violent, as to produce in weak subjects gangrenous necrosis. But when the cure is properly managed in its first stage, the second, or that of suppuration, never occurs; yet, says Rees, the excessive sensitive must be destroyed, and as there is great swelling, though the eye must not be laid to the operation. When the inflammation subsides gradually, in victims of it tends, and even the redness, which is the latest in disappearing, completely goes off in a few days, and the vision of the eye becomes perfect again.

If the cornea and sclerotic into parts, the outer coverings of the eye are quite destroyed, and the consequences are an insupportable extension of the pain (see Catarrhus, or a bare eye (see Catarrhus)). When suppuration happens favorably, the abscess sometimes breaks very well of itself in the outer eyelid; but, according to Rees, this does not readily occur on the lower eye, nor without the formation of a staphylo, which sometimes run quite into the globe. After the abscess has burst, or been opened, the part heals up with great celerity in favorable constitutions, but slowly in others; sometimes granulations arise from the bottom of the cavity, and a cicatricial film which is scarcely perceptible. When the abscess is very large, however, and takes of itself, the upper eyelid may move for some time very much weakened. If the effect of either be neglected, or wrongly treated, or the subject be constitutionally, or the disease be aggravated by the effects of a strong exposure, bad food, severe mental trouble, and passion, or too long continuance of the disease, then, says Rees, there are apt to be produced, sometimes complicated with necrosis of the bone, the serious effects of which are some permanent and lasting weakness of the eye, and the appearance of a fistula. In a division of the eyelid, the eyelid may be a permanent fistula. 2. A strong inflammation of the eye when, with an insupportable itching. 3. A protrusion of the upper eyelid, from distension of the eye by the long continuance of the disease. 4. Inflammation of the sides of the eyelid, from a discharge of its vessels. 5. Extension of the eye, and the eye from loss of skin.

As in this species of inflammation the signs of sight must not be affected, unless the disorder extend itself very much, the exclusion of all light is more than of little use. Laxative purgatives will not be very good, or dangerous, and, as to the eye, and, with the exception of heat, there are to be used; but if the inflammation is attended with febrile symptoms, then they require the necessary antiphlogistic measures.—(Rees, &c. i. p. 275.)

In the second stage, with the exception of a few grains, Rees states, that the cure is to be treated the eye with warm fomentations. When the matter is situated in the middle of the upper eyelid, and for several

the skin, the stream may be allowed to burst of itself, especially if the patient have a great dread of the knife. But if the matter be near the outer or inner canthus, it should be let out with a lancet, as soon as its formation is quite distinct, the incision being made in the direction of the fibres of the orbicular muscle. When fissile or purulent have already taken place, the treatment should be such that which is applicable to the same kind of mischief in most other parts of the skin.

Exophtalmic inflammation of the eyelids usually affects both these parts together, very seldom only the upper one, and never the lower alone. When also both are affected, the disorder always presents itself in the greatest degree in the upper eyelid. A pale, yellowish, watery, transparent, shining swelling arises from the edges of the eyelids, and rapidly extends itself without any determinate boundary, the inner red colour being gradually lost upon the eyelids above, and not so perfectly upon the cheek below. When the inflamed part is gently touched, the vessels disappear, but only for a moment. At length the swelling towards the margin of the eyelids becomes exceedingly soft, and feels like a vesicle that has been raised by a blistering plaster. The pain is insupportable, and attended with itching, but rather with a sense of heat and stiffness; when the part is slightly touched, the patient experiences a lancinating sensation in it. Its temperature is not much increased. The secretions from the Meibomian glands, lachrymal gland, and mucous membrane of the conjunctiva are much increased. In a strong subject, the disorder, if protracted and neglected, is not productive of any constitutional disturbance; but in weak and weak females and children, it is sometimes attended with fever. However, when the symptoms partake of the phlogistic character, and is badly treated, the general symptoms are occasionally very severe at the change from the first to the second stage, and the case may then terminate in a gangrenous kind of suppuration. In infants, delicate children, says Rees, when the disease spreads over the face, the cure requires the most skilled treatment to prevent a dangerous termination.

In strong persons, the second stage of this disorder rarely ends in a violent suppuration, but is rather in an evolution of lymph, which, becoming dry, forms small, delicate, brown scales, in the composition of which the disorganized matter has also a considerable share. In other instances, vesicles of various sizes are formed on the eyelid, and surface, and burst, and discharge a fluid, which is converted into yellowish scales.

According to Rees, the skin of the eyelids is particularly prone to erysipelas inflammation. It is caused by the action of a cold blast of air, or of very cold water upon the skin of the eyelid, while in a state of free perspiration, as the most common cause of its being attended with erysipelas, particularly in weak subjects. The state, however, that the complaint may be terminated by the stage of heat, smart, and other lower accidents, which, when the scales are not retained, are liable to be followed by a violent and dangerous general inflammation of the eye, not infrequently extending to a painful degree to the eyeball itself.—(Rees, &c. i. p. 281.)

With regard to the prognosis, in other cases of erysipelas inflammation as frequently subsides without the aid of surgery as this, provided the constitution be healthy and strong; and when the complaint is confined to its first stage, the vestiges of it seldom are as little as those consequent to necrotic inflammation of the eyelid.

The second stage, however well defined, is followed for a long time by a peculiar sensibility of the skin to the impression of cold damp air, and a strong propensity to relapse. If, when the scales come off, a patient of weak constitution sit in a current of damp cold air, or try to wash away the scales and scales with cold water, then states that an erysipelas affection of the eyelid will be produced, which is often very obstinate, and apt to occasion a temporary inversion of the globe (Trichiasis), or a similar stage of the edge of the eyelid (Ectropion). And he observes, that even from ordinary but obstinate erysipelas inflammation of the eyelid sometimes in suppuration, the abscess is not then a common one, but the matter usually issues in a way, and through several openings in the variety

don of the parts. These pustules indicate the second or suppurative period of the second stage of the case, when either simple or epithelial, or the whole of the surface of the eye is completely becomes inflamed, and serious disease and permanent injury, the new formed places starting successively as the rest is absorbed, particularly in such a manner as to be a conversion of the tissue and pus and structure, thus the patient is afraid of opening his eye. When the patient expects himself, and sometimes in an unhealthy atmosphere, these eruptions of the eye becoming in the suppurative stage are always more extensive; that, they sometimes spread over the lower eyelid and down the cheek.

At length, after this throbbing has lasted, perhaps, several weeks, the suppurative process is checked and suppressed, either by surgical treatment, or accidental favourable circumstances, as change of residence, sea-bath, climate, &c., and then the eruptions immediately diminish. However, a morbid secretion from the Meibomian glands still continues, causing the third period of the second stage, and it is not to become habitual, if not resisted by art, or removed by the effect of accidental favourable circumstances, when it changes into a thin serous discharge, and the inflammation.

Thus, after the course of glaucous inflammation of the eyelids, or simple pustular ophthalmia, in the inflammatory operation of various agents acting chemically upon the edge of the eyelid, and upon the exposed follicles of the glands of the eyelid towards the inner canthus. He says, also, by whom many men are living together in a polluted, noxious air, have suffered with extraneous substances, that form of inflammation is said to occur even in the strongest constitutions with some frequency, that it seems as if it were epidemic. And, according to Beer, the principal cause of the disease will be found to be in the atmosphere, and the next most frequent sources of it, he observes, is acrid exhalations, as coming the eyes with hot water, &c. At the same time, he seems aware that this explanation would not of itself be always quite satisfactory; for he adds, that "although under the above circumstances no contagion, as yet, is supposed, there must be some particular condition which is conducive to the disorder, or at all events to its more rapid and severe course, and the quick extension of the inflammation to various individuals, which condition, he supposes, must depend either upon weakness of constitution, or upon excessive irritability, or, as he thinks it, susceptibility of the whole surface of the body. Beer makes no mention of the effect of damp nocturnal air in warm countries in giving origin to pustular ophthalmia, as much insisted upon by Baglivi and De Vries; but which doctrine, in reference to the origin of pustular ophthalmia in England, I think, completely false; and what is still more worthy of notice, Beer never attempts to resolve the propagation of the disease by its infectious nature. It is observed by De Vries, that the history of all diseases originating from some particular noxiousness received from the atmosphere, but which when spread of propagating themselves by contagion, is considered particularly difficult; because the same circumstances, which favour the communication by contagion, favours also a predisposition to be located upon the more prone causes existing in the atmosphere. The principal cause which gives form and appearance to the eruption of ophthalmia, in the existing individuals together have too limited space. The same circumstances De Vries has seen give a predisposition to diseases of an epidemic, but not a contagious nature; and hence he infers, that it may produce the same predisposition to diseases, which are both contagious and atmospheric.—"The appearance of pustules on the inner corner of the eye and on the cheeks was often met with long before the new destructive and violent disease (pustular) is described. In the story, such ophthalmia has been found to arise spontaneously, without any appearance of the disease except the redness of the conjunctiva; and, while the eye is inflamed, which salutes around the work, as to working in the dark hours, among the same, travail and sleeping more than less in a bed, readily access for the rapid extension of the disease in the same parts, yet the extensive spreading together of parts will effect of itself singular inflammation of the conjunctiva."—(On Diseases of the Eye, p. 71.) I believe, notwithstanding to the extent of all pustular ophthalmia, our present knowledge will permit us to venture an

assertion was the type of the preceding observations, which is, that they originate spontaneously, but probably usually both in this manner, and by the infectious nature of the disease being inadvertently applied in various ways to the eyelids of other persons. This species of inflammation of the eyelids is rarely met with by the surgeon in its first stage, because only very feeble patients then seek medical advice; and most individuals, who seek in other respects well, restore themselves by washing the eyes with cold water, and applying cold poultices, instead of local issues followed in water. Besides, when the disease is not very severe, it frequently subsides of itself; so in favourable constitution, better air is sometimes capable of restoring the healthy state of the eye. If, however, the disease at its commencement should be violent, or attack an individual of very weak habit, Beer states that it may immediately affect not only the Meibomian glands, but the pectiniferous of the cartilage of the eyelid, and produce an incurable ophthalmia, which is also said to take place when the case is neglected, and followed by deeply extending ulceration followed. When the ophthalmia is strictly epithelial, it never brings on any general indisposition, except, by improper treatment; it should happen to be converted into a violent inflammation of the whole eyelid, which, according to Beer, only happens in weak subjects, and women and children, whose state is in a very irritable state, or when a power of apparently good constitution resists under the influence of circumstances which tend to augment the inflammation, as, for instance, exposure to the air of a stable, privy, &c., in which event, Beer describes the inflammation of the eyelids as being quite of a pustular description.

As to the progress in the second stage, Beer observes, that if the eruptions at the suppurative period should spread all over the edge of the eyelids, and caused the patient to keep his eye frequently shut, a partial adhesion of the eyelids to each other (tenesmo-ophthalmia) may be the result. Also, when, at close of the periods of the secretion of tears, or at that of suppuration, the patient is content with merely anointing with warm water the thick matter gluing the eyelids together, so as just to be able to open his eye, and does not thoroughly dry the eyelids from the crass exudate of tears with proper remedies (see Treatment), whereby a secondary inflammation of the conjunctiva of the eyelid will be excited, which, Beer says, should be quickly dissipated from a more extensive of the glaucous inflammation of the eyelid. Such individuals, he observes, may easily become incurable, when the edge of the eyelid is seriously injured by the length of the excoriation. But if the suppurative process be resisted clearly to the pustules, especially the pustules (which case, according to Beer, is not infrequent in old, debilitated subjects of a relaxed constitution), and if the eruptions should deeply penetrate the conjunctiva of the eyelid, this may be completely destroyed, and the lower eyelid ruined.

As to the state of the atmosphere, acrid exhalations, crowded and close places, &c., are considered by Beer to be the principal causes of the glaucous inflammation of the eyelids, or simple pustular ophthalmia, one of the most important indications in the first stage of the disorder, so as to him to be the removal of those noxious influences. And he declares, that if immediate attention be not paid to such indication, it will be quite impossible to prevent a dangerous increase of the disease. A cool fresh air, and bathing the eye with cold water, or a weak lotion of vinegar and water, Beer represents to be means usually adequate to subside this inflammation to its birth. In the second stage, he says, the indication is entirely different.

But also in the beginning of this stage, and even at its second period, namely, that of suppuration taking place, the disorder, according to Beer, ceases for a short time to be benefited by the employment of cold water; but the consequences are avoided by such treatment a great deal worse; for a fresh quick, more extensive inflammation of the same kind again takes place. At the first period of the second stage, viz. while the secretion is a pure mucous and serous matter, Beer says, that it is absolutely necessary to employ such external means, as are calculated to promote the action of the veins and absorbents. For this purpose he recommends the following collimate: R. Ag. rom. Tlb. Hydrag. oxyanat. gr. j. vel gr. drachm. M. ad. em.

part of the cornea has been more or less perforated by the disease, the iris passes through all these openings to be in firm contact with the vitreous body, and the epithelium recedes. In a very short time, not exceeding a few hours, the inside of the iris is affected and turns like the drum, when it is detached, either with or without a portion of the vitreous humor. At length, the membrane detaches, and with it the protrusion of the iris, the opening in the cornea becoming closed with a firm or loose opaque flat cicatrix. But if in this destructive form of suppuration, nothing is done for the relief of the disease, the whole eyeball suppurates, the eyeball becomes covered instead of covered, and the focus between them closes for ever. In cases of badly constituted, when the cure is not properly treated, but persistently in weak children, and excessively violent form of suppurative inflammation, and suppurative epiphora with such rigidity, that a considerable general distention of the system is produced. Indeed, according to M. Trevisan, in the excessive course of the venereal form of conjunctivitis, suppurative epiphora, the system sympathizes; children are considered by a hot and dry skin; and the pulse is frequent and hard. Yet it is particularly pointed out by the same surgeon, that the possibility of the Egyptian patients to be in their generally attended with little constitutional disturbance. When the above described condition of the eye takes place, it is a warning to violent general inflammation in weakness, weak children, and even to some extent by a long while referred to an impaired state of health.

According to Beer, who appears to have no idea of venereal being venereal, the particular cause of this unfortunate extension of idiopathic glandular inflammation of the eye, both in infants and adults, frequently depends upon the fact that the eye is in a state of irritation and hence, says he, the disorder is in its first stage, is by a long and tedious process, where the eye is much contaminated by infection from the milk, the crowding together of many irregular persons, dry clothes, &c. The unclean state of exposing the eyes of infants to the rays of very dirty light, a woman knows, in which the child's head is covered a long while in the vagina, and usually washing the eyes after birth with a coarse sponge, and other circumstances supposed by Beer to be conducive to the origin of the complaint is now-born infants. The severity of many of these cases I regard myself with a good deal of doubt, and as far as the cooperation, that sparkling cold water in the head is required, which is a cause of periorbital, may produce the complaint, it is also plausible to find any venereal infection. The disorder, he says, is always more rapid and profound in new-born infants than adults (J. L. p. 266). It is evident which does not agree with the statements lately made, if the Egyptian ophthalmia, as well as the way, be considered. It is noticed by M. Trevisan, that the highly contagious nature of the suppurative ophthalmia, whether in the infantile venereal form, is sufficiently proved. For one person, affected with this disease, above three months old, he thinks at least twenty are attacked under his age. The manner in which it is first stage, of gonorrhea, and the disease is usually perceived about the third day. (Acquisit. Ac. p. 97.) Some further observations on the causes of some of these severe modifications of glandular inflammation of the eye will be introduced, after the general and common have been considered. This will be the more necessary, as the progress of the disorder by infection is here entirely overlooked.

According to Beer, whenever an idiopathic inflammation of the glands of the eye, arises the eye is first attacked in the suppurative ophthalmia of infants, the Egyptian ophthalmia, and gonorrheal ophthalmia, the progress must naturally be venereal, and this in a greater degree, the more the inflammation is and suppurative have extended to the eye itself. The same eye and even suppurative, when they happen in post, but, contrary, observed sometimes when it is venereal, also suppurative to extend from the inflammation which either arises, or has a previous effect upon, the disease. Should an accidental infection not be immediately noticed, says Beer, it will continue until the end of the second year, and even long after, as in the case of particular treatment. When the period of suppuration, which is the last of the conjunctiva

spread over the cornea is destroyed, the progress, in respect to the suppurative progress of the eye, is favorable, although it takes place but slowly. If the effects of the disease at this period should be deeper, yet the cornea not destroyed, only rendered flat and somewhat opaque; or if the cornea should be elevated at a very limited point, there will remain, in the last case, an opacity of the cornea; but in the second, a partial adhesion of the iris to the latter membrane (synechia anterior) is apt to follow, with a more or less extensive, situated on the cornea, covering it a greater or less degree the humors and displaced pupil, and thus discharging as preventing vision. When, during the inflammation and suppuration, a considerable part or the whole of the iris adheres to the cornea, and this is not prevented by absorption, the result, in the first case, is a perforia, in the second, a complete proptosis of the cornea, which does not fully develop itself until towards the decline of the second stage of the inflammation. If the inflammation should spread to the tissues of the eyeball itself, so as to produce severe constitutional disturbance, the eye would away in the midst of the process discharge, the system sink inwardly, and the distance between them becomes permanently closed. (Beer, J. L. p. 219.)

Beer, makes the opinion of the celebrated Stenstrom, which was, that the ophthalmia, in particular, suppurative, involving the sclerotic membrane, always has a first duration of a month, in new-born infants, and of six, eight, or twelve weeks in adult individuals. Beer acknowledges the correctness of this opinion, only in cases where the suppurative has to deal with a suppurative (suppurative) inflammation, and not in a more recent case, or one in which the disease is chiefly confined to the tissues of the eye. (Idem—Stenstrom.) When the disorder is not with in the first period of the second stage, or it is confined to the suppurative suppurative and venereal glands, and truly suppurative, Beer asserts that it cannot stay, be restricted by efficient treatment to a few days, as he has often proved in the establishment of the hospital in Vienna.

It is further remarked by Beer, that in this modification of venereal suppurative inflammation of the eye, the indications have according to him, in these. If, by chance, the eye is not with the disease in its first stage, it will be more benefited by the application of cold water, wet with cold water, and sometimes a brisk purge of jalap and calomel, and putting a leech over the internal side of the lower eyelid, will promote the subsidence of this dangerous species of ophthalmia. The cure, however, easily prevents itself for medical treatment than early, and in hospital, Beer says, antiphlogistic treatment is, on this account, hardly ever indicated.

With some exceptions of importance, the treatment advised by Beer, for the second stage of these severe forms of gonorrheal ophthalmia, involves that proposed by him for the second stage of simple idiopathic inflammation of the eye, in the earlier stages. These more severe kinds of venereal inflammation of the eye, implied by Stenstrom's treatment and ophthalmia-venerea, he says, should never be allowed and treated merely as local diseases; but that, both in children and adults, internal remedies should be exhibited, particularly saline medicaments. In cases where the cornea is already attacked by a destructive ulcerative process, mercurial exposure has proved him thus best, combined with mercury, and the discharge of pus, is the only means of saving the eye; but that, if the suppuration be confined to the eye, the direction of external treatment with mercury and opium will usually prove. When, as the experience of suppurative, the pain is the eye and neighboring parts is extremely severe, Beer asserts, that friction with a liniment of opium will give great relief. In new-born infants, the external use of mercury will mostly do more good than internal medicine; but if the case be urgent, and the child feeble, Beer thinks venereal medicines may sometimes be useful.

With regard to particularities, while recovery is the local treatment by the method above of the inflammation, Beer offers the following information: first, in new-born infants, or very young children, the experience of mercury cannot be used without danger, should be used with caution; and even in adults it should be employed in these cases with great care.

specimen. Secondly, the water and purulent matter should not be allowed to remain long under the eyelids, as such impurities tend to promote the destruction of the layers of the conjunctiva situated on the cornea; but at the same time, those fluids, that having any weight on the eye, after cleansing them, and letting it become cold there, will have quite no pernicious effects. Hence, in a very particular manner, all the mucus and purulent matter to be swept away from the eye with a bit of fine sponge, moistened with a warm watery saline solution, but not so wet as to let the fluid drop out of it; or when they are very copious and in large flakes, be even recomended to be washed away by means of Angel's syringe; but he says that every part about the eye should be immediately afterwards well dried with a warm napkin, and then covered with a warm camphorated ointment. Thirdly, during the supplicative period, according to Beer, constant friction of opiate, or the viscus tincture, is the best local application, the part being washed with it twice a day, by means of a fine clove-brush. It is only in a few instances, that a small proportion of the aqueous distillate (see *Ischaemic Oedema*), mixed with the watery saline solution, can be used. Beer declares that the best ever seen any good produced by them; that the best is that which was slightly prepared by means Mr. Ware. Fourthly, when the supplicative period has terminated, the mucous secretion again becomes white and thin, as at the very commencement of the second stage, but it is always more copious; now, is the time, as in the last stage of simple phlegm, inflammation of the eyelids when the topical use of mercury, joined with styptic, especially in the form of an eye-salve, is indicated. Fifthly, if an eversion of the upper eyelid should happen from washing the eye constantly, or the mere crying of the infant, by consequence of the thickened granulated state of the palpebral conjunctiva, the position of the eyelid must, if possible, be immediately rectified; for otherwise this defect is done. In order to avoid this eversion, the eyelids should never be opened while the child is crying, or in any way agitated. For at such periods, the thickened sclerotic conjunctiva will suddenly protrude, and cannot be kept back. Beer says, that the eyelid should be replaced in the manner directed by Schmidt.—(*Ophthalm. Hist.* 3, 4, 2, book p. 493.) The surgeon, having removed the coat of the tarsus and fore-layers of each of his lids with flesh force, is to take hold of the everted cuticle of the eyelid in the outer and inner canthus, draw it slowly a little upwards, and then suddenly downwards. The thickened conjunctiva, if not too fleshy and granulated, may be quickly reduced, and the corneal surface exposed. But if the swelling of this membrane should be already very considerable, and have begun to be hard and studded with excrescences, the thumbs should be placed so as to compress the middle of the eyelid. However, if the corneal surface be so much affected, it is to be treated, after the termination of the second stage of the puerile ophthalmia, in a series of this manner.

—See *Ectropion*.

In the ophthalmia-blennorrhoea, the alteration of the sclerotic conjunctiva is said by Beer to be very different from chemosis; a chemosis which is merely correct, inasmuch as cellular chemosis is not attended with thick change in the surface of the sclerotic conjunctiva, which first is the secretion of pus. But if we are to understand by chemosis a copious effusion of lymph in the loose cellular substance between the conjunctiva and the eyelid, this state must be observed in one of the usual effects of severe puerile ophthalmia.

"It is under this usual condition, which is characterized by the suppurative ophthalmia says Mr. Travers, that the conjunctiva first assumes excrescences, granulations, then, in hard cases only, protruding between the palpebra and globe, and covering the latter, as, if not destroyed, causing the turning of the lid over the eye globe. The third period takes us from the same state the hard granulated surface, which keeps up increased irritation of the sclerotic conjunctiva, and at length reaches the corneal epithelium."—(*Travers*, 47, p. 385.)

The treatment recommended by Mr. Travers for the venous and arterio-venous inflammation of the conjunctiva, consists in a very copious hemorrhage, by which, he says, the pain is mitigated, if not removed, the pain abated; and the patient sinks into a sound

sleep, and purifies freely. The high morbid heat and bulk of the chemicals are thereby reduced, and the system is lightened. The blood being, if necessary, it is to be repeated, and the patient kindly purged, every day of the opening venous being followed by a transfusion of a mixture of arsenic, tartar, or so to keep up a state of tension, perspiration, and resolution. When the discharge becomes thick, grey, and from chemosis, the swelling of the eyelid subsides, the conjunctiva sinks and becomes pale and fleshy, the pain and local irritation are past, and the cornea returns to its usual brightness. Mr. Travers remarks the same day, and states that the prompt subsidence of mucus, with the use of feeding and digesting lotions, will prevent its passing into a chronic form. "But if, when the bleeding practice has been pushed to the point of effusion, some inflammation, the patient being at the same time weak and exhausted, the cornea shows a dark stain and appearance of its whole surface, as if it were by immersion in an acid, or a gray stain in the centre, or a line extending or half-extending in line, assuming a macular appearance, the patient is washed out with facility by detached by a rapid double vision it is a decided sign of the puerile blennorrhoea, being an indication of catarrh, so as to produce in it that which may render it permanent."—(*Travers*, 47, p. 385.) Here we find some approximation of opinion between Mr. Travers and Professor Ross, for the almost the only point at which any resemblance can be found in their modes of treatment.

The granulated or fungous state of the palpebral conjunctiva, produced by puerile ophthalmia, sometimes demands particular treatment when the original disease is subdued. If such state of the eye be not subdued, it often keeps up a "glazy discharge," unsuitable to light, dropping of the upper lid, a pricking sensation as if sand in the eye, and a permanently troublesome and vascular state of the sclerotic conjunctiva. With these are frequently combined symptoms of the cornea.—(*Travers*, op. cit. p. 221.) The effusion, as compared with opaque cornea, is particularly noted by Dr. Vetch, who describes the disease of the pupil as consisting, in first, in a highly vascular state of the vascular tissue, which, if not treated by appropriate remedies, gives birth to granulations, which in process of time become more deeply extended, hard, or warty. Along with the effusion and thickening, and of the lining of the eyelid, there is a gradual ejection of purulent matter, which may at any time be squeezed out by pressing the finger on the eye. The deepest structure is highly vascular, and strongly protrudes when cut. It processes, and granulated substances do a very great extent of growth, or multiplication. Dr. Vetch has seen many cases in which it has been removed with ease and this function, many or thirty times successively, without the disposition to reproduction having suffered any diminution. Indeed, he assumes as that the operation will very effectually be the ultimate recovery of the pupil. "A new surface is produced of a highly vascular appearance, much less susceptible of cure than the original disease, and often, even if it is locally treated, does not assume the natural appearance of the part, but that of a elevated surface," not attended with a return of the transparency of the cornea. It is notwithstanding proved by the observations of Dr. Vetch, that granulated growth of the inner surface of the eyelid was not only seen in children and other and paratubercles, under the name of leucophaea, leucos conjunctivae, &c., but may be known by the actual history, extension, and growth, and also recommended by them. The benefit of this operation is the probable state of eye with respect to it. Dr. Vetch states in 47, that no treatment appears to Dr. Vetch more efficacious for this disease than the exposure of copper and nitrate of silver. "It says that they should be pointed in the form of a point, and fixed in a perforation." "They are well applied, not as others have conceived, with the view of producing a scab over the whole surface, but with great delicacy, and in so many points as to well produce a gradual change in the condition and disposition of the part." As long as any granulated growth of Vetch states that the above operation will be well suited by the daily use of the leucophaea solution. When the disease returns some resolution, and the eye is to be hard and watery, he applies very minute quantities of finely-digested powder of vitriol, or lead

alone, to the inverted surface with a few dried hair pencil, but usually rather than off with a syringe before the eyelid is required. The caustic pencil, lightly applied to the more prominent parts of the diseased surface, will also answer.—(See *Poissin on Diseases of the Eye*, p. 73, &c.) Mr. Lloyd also gives his testimony in favour of the superiority of the nitrate of silver, which he has employed in the form of a saturated solution for restoring the healthy state of the inner surface of the eyelid.—(On *Scrofula*, p. 328.) The practice of excision was followed by the ancients, and revived of late years in England by Mr. Keen, who, with almost what Sir W. Adams and others have subsequently performed with a knife or bistoury. Mr. Travers, I may observe, is also one of the advocates for the excision of the granulations and hardened integuments of the conjunctiva. If there be a rotundity of the cornea, with a placid of vessels extending to it, there are then divided near the edge of the cornea, in the manner recommended by Scarpa. Mr. Travers afterwards applied a solution of the sulphate of copper, the tincture of iodine, or the strong tincture of opium. The remark which he makes tends very much to confirm the general advantage of the practice introduced by Dr. Vetch; for, it is observed, "the application of the blue-stone, or of the lunar caustic, is often useful in preventing the regeneration of the granulations after their excision."—(*Synopsis*, &c. p. 221.) My friend Mr. Lawrence, whose experience in diseases of the eye is a very considerable, informs me that he finds caustic the more modest of practitioners reserving the granulated fungous state of the inner surface of the eyelid, and that, when the granulations are not away, they are frequently reproduced; a fact to which Dr. Vetch has justly justly assigned.

Egyptian Ophthalmia. One of the best accounts of this disease, as it appeared in the army, is that delivered by Dr. Vetch. Although there can be no doubt that the disorder, in all its general characters, closely corresponds to the whole class of acute conjunctival inflammations of the conjunctiva, as described by Boerhaave, yet it has some peculiarities. Thus, one thing noticed in the Egyptian ophthalmia, but not in other purulent ophthalmias, is, that the first appearance of inflammation was always in the lining of the lower eyelid.—(*Poissin on Diseases of the Eye*, p. 100.) According to the latter writer, the degree of cut of nasal rolling in the eye, is a symptom requiring particular attention, as its occurrence in a certain index of the disease being on the increase. It is subject to exacerbations and remissions, the attacks always taking place in the evening, or very early in the morning. The first stage of the disease is said by Dr. Vetch to be characterized by its progress uniform redness, without that pain, burning, or intolerance of light, which is common to most other forms of ocular inflammation; and, in particular, that in which the sebaceous root is affected. From the very beginning of the complaint, there is a disposition in profusion in the cellular texture between the conjunctiva and the globe of the eye, often suddenly swelling up into a state of complete thrombosis, and at other times making a more gradual approach to the cornea. While effusion is then taking place upon the eye, motion is likewise going on beneath the integuments of the eyelids. The excessive transudation of the eyelids is said to be generally commensurate with the complete formation of chemosis; ectropion is produced, and the integuments of the two eyelids meet, leaving a deep cleft between them. When the external swelling begins, the discharge, which was previously moderate, and consisted of pus floating in a watery fluid, changes into a copious stream of yellow matter, which, mixed with the hardest secretion, greatly increases in quantity that derived from any position. Although, says Dr. Vetch, the inflammation may be at first limited to one eye, it soon invades the other, it generally reaches its greatest height in both about the same. The patient never began to suffer from attacks of characteristic pain in the eye, a certain indication of the extension of the attack. "An occasional remission, as if motion were threatening the eye, accompanied with sleep and freedom of the eyelids, often precedes the deeper-seated pain." This is often of an alarming nature, and a period of supplicating torture is succeeded by an interval of pro-

fect ease. Sometimes, the pain shifts intermittently from one eye to the other, and is seldom or never equally severe in both at the same time; and sometimes, instead of being in the eye, it occurs in a circumscript spot of the facial, which the patient describes by saying he can cover the point with his finger. Sometime or later, one of these attacks of pain is terminated by a cessation of rupture of the cornea, with a rush of scalding water, succeeded by immediate relief to the eye, in which this wound has happened, but generally soon followed by an increased violence of the symptoms in the other. At length, the attacks of pain become shorter and less severe, though they do not cease altogether till after the lapse of many weeks and even months. During this stage of the disease, according to Dr. Vetch, there is seldom the slightest alteration of the pulse, unless the lowest have been formerly employed. The patient's general health is little impaired, his appetite remains rational, but sleep almost totally forsakes him.

As the pain abates, the external transudation also subsides; and a gaping appearance of the eyelids succeeds; their edges, instead of being inverted, now becoming everted. This is what Dr. Vetch designates as the third stage of the disease.

After the swelling of the second stage has subsided, the eyelids are prevented from returning to their natural state by the continued change of the conjunctiva which takes place; and an extension of their normal position is a greater or less degree.—(*Poissin on Diseases of the Eye*, p. 200, 201.) Among most interesting remarks made by the same author, in stating, that there is no reason to warrant the idea that the inflammation proceeds from within outwards. He observes, that when any large portion of the cornea sloughs, an adhesion and vascular membrane is often produced, which finally forms a staphyloma. In some few cases, says he, I have seen the lens and its capsule exposed without any external covering whatever; and, for a short time, the patient can see every thing with wonderful clarity; but, as soon as the capsule gives way, the lens and more or less of the vitreous humour escape, the eye shrinks, and the cornea constantly takes a small horn colored spot." This total destruction of the globe of the eye is said generally to smother the other, and renders a less liable to be affected by future attacks of inflammation.

A few years ago an ophthalmia, supposed to be of the same nature as the Egyptian, though milder, like that which has generally been observed in schools, occurred to a great extent in the Royal Military Asylum at Chelsea, and Sir Patrick Macgregor, the surgeon, observed the public with an excellent disposition of the disease, and some highly interesting facts and reflections upon the subject. The symptoms generally made their appearance in the following order: "A considerable degree of itching was first felt in the evening; this was succeeded by a sticking together of the eyelids, principally completed of by the patient on waking in the morning. The eyelids appeared thicker externally than they naturally are; and on examining their internal surface this was found inflamed. The subconjunctival glands of the nasal were considerably enlarged, and of a redder colour than usual. The external lachrymalis had a similar appearance."

In 1810 to 25 hours after the appearance of the above mentioned symptoms, a violent mucous discharge took place from the internal surface of each eyelid, and lodged at the lower margin, till quantity was sufficient to be pressed over the cheek by the motion of the eye. The vessels of the lachrymal conjunctiva covering the eyelid were discoloured with red blood, and the lachrymal conjunctiva was generally in thickened and raised as to form an elevated border round the transparent cornea. This state was often accompanied with motion of the globe against the eye, which sometimes extended to a considerable distance, and resembled in colour and in a very much what takes place in the cow pox pustule, between the ninth and twelfth days after inoculation.

When the purulent discharge was considerable, there was a swelling of the external eyelids, which often prevented the patient from opening them for several days. The discharge also incessantly accompanied the cheeks as it trickled down. Exposure to light caused pain. When light was excluded, and the eye kept in darkness, pain was seldom much complained of.

* These symptoms in many subside without much aid from medicine, in 12, 13, or 14 days, leaving the eye for a considerable time in an irritable state. In several, however, the disease continued for a week longer, and sometimes took place on the internal surface of the eyelids, and in different parts of the eyeball. "If one of these eyes is supposed to be attacked in the transverse channel, it generally, on looking, left a white spot, which, however, in the young subjects under our care, was commonly even observed. In some few instances an elevated cock-plum on the substance of the eyeball, which, baring externally, produced irreparable blindness."—(See Treatise for the Improvement of Mind, and Char. Knowledge, vol. 2, p. 31—40.)

When the third symptom had prevailed beyond three days, some fatal disturbance occurred. And, except in seven cases, it was nearly always fatal.

Dr P. McGee considered this ophthalmia to be of the same nature as that which raged with such violence in the army at different periods, after the return of hot troops from Egypt in 1802, 1803, and 1804. However, he found that its consequences were not so injurious to children as to adults; for, out of the great number of children afflicted with this disease at the Hospital, only six lost the sight of both eyes, and twelve the sight of one eye.—(Op. cit. p. 43.) On the other hand, Dr. Vesalius informs us, that in the recent epidemics in the Mediterranean, which consisted of somewhat more than 200 men, 626 cases of ophthalmia were observed; and the highest numbers, August, 1805, and August, 1806; and that "of this number, fifty were diseased with the loss of both eyes, and fifty with that of one." And as Dr P. McGee observes, it is a particularly fatal, in appearance from the return of Eastern and Mohammedan troops, that 2117 soldiers were, on the 1st of December, 1811, a victim to the epidemic, and blindness in consequence of ophthalmia. The cases in which only one eye was lost are not here included.

The attack of the disease appears to be least more frequent, severe, and obstinate, in hot, sunny weather, than in cold or temperate seasons.—(Op. cit. p. 27, 34, 40.)

Dr P. McGee also observed, that the ophthalmia sometimes began and continued in persons of hot temper, or a sanguine habit, than in others. The right eye was more frequently and severely affected than the left. In several, the symptoms were greatly aggravated for some days previous to the commencement of the examination taking place, they were quickly relieved. Dr P. McGee further remarked, that the disease, not only, and perhaps even through their means, is frequently in persons affected with this species of ophthalmia, so when no other disease was present; a circumstance which, with some others, prove that the disorder was entirely local.—(P. 34, 35.)

With respect to the causes of the Egyptian Purulent Ophthalmia, much difference of opinion has prevailed, and indeed there was a time when the disease was regarded by the majority of many writers, who also distinguished the epidemic from local epidemic causes; the irritation of sand; the activity of climate, &c. The late Mr. Ware even doubted the propriety of calling this ophthalmia Egyptian, and he concluded that the disease, previously similar to its symptoms and progress, had been noticed long ago in Asia and other parts, and that, in Egypt, several varieties of ophthalmia prevailed. He suggested calling the disease the Egyptian Purulent Ophthalmia. On the other hand, Dr W. Adams conjectured, that it ought rather to be called Asiatic Ophthalmia, as several investigations prove that it prevails in the greater part of Asia, and was long ago described by Aesculapius.—(Graefe, *Journal*, vol. 1, p. 179.)

That this disease has long been in this country as infectious species of purulent ophthalmia, cannot be doubted. The one described by many surgeons, as proceeding from the sudden escape of gonorrhoea, or the undiminished application of gonorrhoeal matter to the eye, which always will be properly noticed, is certainly an infectious purulent ophthalmia. It is also found in infectious purulent ophthalmia, by the admission, that infectious purulent ophthalmia, by the intensity and rapidity of its progress, but the latter is strongly characterized by the epidemics with which it is associated, especially in adults, opacities, or al-

terations of the cornea; the long continued irritability of the eyes after the subsidence of inflammation, but more particularly the very infectious nature, by which it spreads to any extent that may arise from infection with regard to any other species of purulent ophthalmia. There have been epidemic ophthalmias of other kinds which have been known to affect the greater part of the population of certain districts and even in Asia. The celebrated ophthalmia which raged in Newbury, in Berke, some years ago, is an instance that must be known to every body. But I know of no infectious inflammation of the eye, which ever spread to a great extent in England, before the return of the troops from Egypt.

The infectious and observations of Sir F. M. Owen, as well as those of Dr. Vesalius and Dr. Edmonstone, I think, leave no doubt of two facts: first, that the ophthalmia was of all kinds brought from Egypt, and, secondly, that it is infectious. And only on the basis of being communicated from one person to another by actual contact of the discharge. "If says Dr. Vesalius, my belief, more sustained by the effects of the Egyptian army, during the first expedition to Egypt, that the disease was contagious, it was of a nature very rapid and obstinate. Combined as its operation is extremely violent, and as that country much more healthy than ours, there would be more difficulty in the first introduction of the fact. But the continuance of the complaint with the troops after their departure from the country, could scarcely fail to lead to the obvious conclusion of its possessing a power of propagation. Hence the disease reached this country, the opinion of its being contagious was adopted by many. Dr. Edmonstone, in the account which he published of the disease as it appeared in the regiment to which he was surgeon after its return to England, first made the public acquainted with the fact of the disease being contagious. It is an account of the Egyptian ophthalmia, as it appeared in this country, printed in the early part of 1805. I first established, that the communicability of the disease was exclusively produced by the application of the discharge from the eyes of the diseased to that of the healthy."—(On Diseases of the Eye, p. 179.)

The opinion, that the disease is not communicated from one person to another, through the medium of the atmosphere, is at present nearly abandoned. Being the whole time that Dr. Vesalius had the management of the ophthalmic hospitals, there never was an instance of any medical officer contracting the disease, although exposed to what might be supposed to be the greatest concentration of the contagion that could arise in the most stage of the complaint. Two ophthalmias only contracted the disease, and both in consequence of the actual application of the virus. However, Dr W. Adams maintains, that he has seen many cases, which prove that the disorder, like small-pox, may spread naturally without any kind of inoculation.—(See Graefe's *Journal*, vol. 1, p. 174.) That the disease may be partly propagated by epidemic causes in particular situations, I think is certain and clear, so that there may be a true for the first communication of the disorder in situations where infection by contact is not of the parties. And as Dr. Vesalius has observed, "from whatever cause the inflammation of the conjunctiva and cornea, when the active is of that nature, or degree of violence as to produce a purulent or purulent discharge, the discharge, as good and operates as an infectious virus, when applied to the conjunctiva of a healthy eye. Considering the various modes by which such a contact may inevitably occur in the usual relations of life, it must be evident, that wherever ophthalmia prevails, whether it be the effect of local conditions of the soil or of the atmosphere, naturally or artificially produced, this contagious element sooner or later, but as it is in contact with that of the more general and original cause, and hence, without regard to this point of the disease, its transmission must often operate imperceptibly, and at variance with the more general cause, either in external circumstances. And, further, as the disease is moderated by temperance is of a nature more violent and malignant than that produced by the exposure of a conjunctiva to the air, it will, in every instance of excessive purulent ophthalmia, operate most different forms of disease, which, as long as they are continued as long and the more, will produce, according as the one or the other predominates, very different results."—(On Diseases of the Eye, p. 179.)

Dr F. McGregor relates three cases, which prove that the matter, after its application, produces its effects in a very short time. I shall only cite the following example.—On the 2nd of October, 1855, about five o'clock, p.m., Naomi Parnoody, while spraying the eye of a boy, let some of the lotion which had already washed the diseased eye pass out of the syringe into her own right eye. She felt little or no stinging at the time; but towards nine o'clock the same evening, her right eye became red and somewhat painful, and when she awoke next morning, her eyelids were swollen, there was a painful discharge, pain, &c.—(Op. cit. p. 51.)

The late Mr. Ware, though he admitted that the infection was brought into this country from Egypt by the troops, conceived that the same disease also sometimes arose from the matter of gonorrhoea being applied to the eyes, and that it had been prevalent in this country before the arrival of the army from Egypt. He thought, however, that the infection was generally communicated by contact. Mr. Ware observes, some of the worst cases of the purulent ophthalmia of children have happened in those whose mothers were subject to an acrimonious discharge from the breasts at the time of parturition. Some of the worst forms of the purulent ophthalmia in adults have occurred in those who, either shortly before the attack of the ophthalmia or at that very time, laboured either under a gonorrhoea or a gleet. Mr. Ware does not mean to suppose every purulent ophthalmia to be such a case; but in the majority of adults whom he has seen afflicted, if the disorder had not been produced by the application of morbid matter from a diseased eye, it could be traced to a connection between the ophthalmia and disease of the urethra. Other causes, Mr. Ware acknowledges, may contribute to aggravate, and, perhaps, produce the disorder, and the purulent ophthalmia in Egypt has been imputed to a great number. The continued influence of heat and light, of a burning day, continually rising by the wind, and of the heavy dew of the night, may powerfully tend to excite inflammation of the eyes. Yet something more necessary to account the malignant ophthalmia now under consideration, for the same causes operate with equal violence in some other countries besides Egypt, and yet do not produce the same effect; and in this country (says Mr. Ware), the disorder prevailed during the last summer to no great degree, and upon as great a number of persons, within a small district of less than a mile, as it ever did in Egypt; and yet, beyond this space on either side, scarcely a person was affected with it. The disorder was certainly brought into this country by the soldiers who returned from Egypt, and was probably communicated from them to every soldier. Now, as the action of the atmosphere alone cannot account for the spreading of the disease, &c., Mr. Ware is led to believe, that this particular disorder is only communicable by disease vessels; that is, by the application of some part of the discharge which issues either from the conjunctiva of an affected eye, or from some other morbid secretion in similar position, to the conjunctiva of the eye of another person. In schools and hospitals, in consequence of children using the same basin and towels as others who had the complaint, the disease has been communicated to nearly twenty in one instance. Hence, Mr. Ware considers the instructions to use of these articles in schools, hospitals, barracks, ships, and barracks.—(P. H. G.)

That in Egypt the origin of the disease cannot properly be traced to the effect of the sand and hot winds of the country is clearly proved; but, because, if this were the case, the disease would not be more prevalent in the external season during the introduction of the Nile. Mr. Ware infers that the disease would not be more subject to it than the Bedouin Arabs, who live on the banks of the desert. Not only the Bedouin Arabs, says Dr. Vetch, remain free from the disease, but Europeans also are not particularly exposed to it, though they are also liable to its attacks. The nature of military duty prevented our soldiers from using this precaution, and in a particular manner they became victims to the complaint. The men suffered more in proportion to the influence of the English army; as the heterogeneous, better thought men in insubordinate defiance than the soldiers and domestics of the native, and officers employed in military duty suffered more than those attached to the civil de-

partments.—(Vetch on Diseases of the Eye, p. 137.) And Asselin remarks, that if the dust or sand were the sole cause of ophthalmia, we ought to be exempted from the disease where the cause does not exist. The contrary, however, was the case in the Delta, and particularly in the cultivated lands of the Nile during its inundations. When we were exposed to the air during the night, we were immediately attacked with ophthalmia, though the dust and sand were then under water. Lavery was exposed to the origin of the disease in the cold, damp nocturnal air after the great heats of the day.—(Graf's Journ. i. 1, p. 133.)

Whoever reads the account of the Egyptian ophthalmia, as given by Dr F. McGregor and Dr. Vetch, will be convinced, that the disease is only communicable from one person to another by the application of the infectious matter to the eyes. Probably the common mode of propagation is the introduction of the same matter, or even merely touching the same articles which have been in the hands of infected persons, who must be supposed occasionally to apply these fingers more or less to the eyelids. In this way, the communication of the disease may be accounted for in instances upon their entering into barracks which have been visited by other infected soldiers. "Fever, in warm weather (says Sir P. McGregor), are seen in great numbers surrounding patients labouring under ophthalmia; and I much suspect the very frequently the medium by which the disease is propagated."—(P. 24.) The matter is observed to become infectious when the disease is in an acute state.

Dr. Vetch adverts to two important questions connected with the history of the Egyptian ophthalmia. The first relates to the length of time which the disease has, at different periods, lain dormant, and especially between the return of the troops from Egypt and the breaking out of the disease in the 20th regiment. An explanation of this fact is attempted by supposing that the complaint exists, and is liable to a renewal of its infectious quality, long after the eye seems to have recovered its natural and healthy appearance. Perhaps it would be as well to be content with the fact, that in crowded barracks, under particular circumstances, soldiers who have once had the disease are very liable to relapse. The other question is, why has the disease produced such ravages in the army in England, and not in that of France? It is well known that the French soldiers in Egypt suffered as much as our own troops from the affection, and great numbers of them returned to France with the disease in a chronic form. "In fact (says M. Roux), the influence of their native climate has sufficed for the removal of all vestige of the disorder. On the contrary, in soldiers it has continued in a chronic state, either attended with the loss of one or of both eyes; and many of our invalids remain with the affliction. But it has not been found, that those soldiers who returned from Egypt have ever communicated a contagious ophthalmia, either in regiments as well as many of them have been incorporated, or in invalid battalions, where others have obtained their retirement; or in the individuals belonging to the different classes of society. Such is the objection that has been made, and may always be again urged, against the opinions and conclusions of the English, respecting the Egyptian ophthalmia."—(Ferguson's & Lombard on 1814, on Paralysis de la Vue, &c. p. 45.)

Lavery, who admits that the disease may be communicated by application of the matter, argues that it is not contagious in any other way, because, in Egypt, for want of sufficient hospital room, patients with this and other diseases, were crowded together without the ophthalmia being propagated to any of the patients, who were careful to avoid the above mode of infection.—(Graf's Journ. i. 1, p. 133.) Lavery, however, need not have used this reasoning with us, because it is unnecessary to him to suppose, that the disease is here continually revived in communicable through the medium of the atmosphere. While, however, English surgeons chiefly explain the extension of the disease by the infectious matter of the discharge when applied to the eyelids, and Lavery admits that the matter is thus infectious, the latter, as well as Roux, assumes that none of the healthy soldiers who came home with the blind invalids from Egypt were attacked with this species of ophthalmia. A great number of these invalids were received in the hospital of the gendarms at

them, and treated them without any of the other poisons being infused.—(*Gazette's Journ.* Jan. 20.) On my return from the Mediterranean through France, in 1802, I saw many of the French troops at Aix and Avignon with bad eyes, contracted at Egypt, notwithstanding with other soldiers, whose eyes were perfectly healthy, and living in the same barracks; a proof that the French soldiers, with the exception of camels, or some other poisoning cause, were placed apparently in circumstances in which the disease here made such extensive ravages. This is a point which I hardly conceive is not at all alluded to by Dr. Vesali's belief, that the difference is principally by the French troops being sent into the field; for, in fact, the soldiers with diseased eyes were in barracks or hospitals as well as our own troops.

But notwithstanding it seems proved, that the discharge from the eyes in the Egyptian ophthalmia is so actively infectious in England, it appears from an experiment, made by Mr. Mackenzie, that the application may sometimes be made to a healthy eye without the disease following as a matter of contagion; for he applied to his two eyes liquor impregnated with matter discharged from the eyes of patients in the fully formed stage of the disease, and even altered some of the matter in pus under the eyelids, yet the complaint was not communicated.—(*See Edinb. Med. and Surg. Journ.* vol. XL, p. 441.)

One of the most natural circumstances in which the practice of English surgeons differs from that of foreign practitioners in cases of severe purulent and especially Egyptian ophthalmia, is the frequency and boldness with which the former attack the disease in its first stage. Mr. Ferri recommends taking away at once as much as 60 minims of blood (*Edinb. Med. and Surg. Journ.* for January, 1807); and Dr. Vesali lays great stress on the striking benefit of bleeding the patient till syncope is produced. "When inflammation in the seat in the subacute point (says he), general blood letting may for the first part be dispensed with, and even when employed to the greatest extent, the same benefit does not ensue. In the purulent inflammation of the conjunctiva, however, although some good may be derived from depletion, yet a perfect cure over the disease depends less on lowering the system than on the judicious control of acridal action by eversion, which it becomes the object of the operation to produce. This position, besides its efficacy, will accompany the cure with a much less expenditure of blood than is occasioned by the repeated bleeding constantly and because to whom this method of rendering one equal to the cure of the complaint has been rejected. Some time before the approach of darkness the surface of the conjunctiva for the most part disappears; but this is no security against the return of the disease, if the flow of blood be stopped, without delicate and steady attending."—(*On Diseases of the Eye*, p. 398.) The attacks of a painful granulation, as if poured more in the eye, in some cases as a proof of the disease increasing, and, in the early stage of the disease, as a better indication of the necessity of bleeding, than the appearance of the eye itself.

With respect to applications, Dr. Vesali speaks very highly of the beneficial effects produced in the beginning of the case by dropping into the eye the undiluted liquor plumbi subacutale, which, he says, dissolves the discharge, lessens the inflammation, and is incapable of doing harm in any stage of the disease. He places great confidence in the salutary results of a free exposure of the eye to the atmosphere, and speaks in high terms of the good derived from applying at night to the eye an infusion of tobacco; thus declaring the leaves to emit vapors of water. "It possesses large Dr. Vesali the valuable properties of acting as a powerful anæsthetic, removing the purulent discharge, and dissolving the albumen or external swelling of the palpebra; at the same time that its narcotic qualities often remove the pain and the purulent granulations which the largest doses of opium cannot relieve."—(*P. 411*.) Bleeding, however, is the "chief remedy," and the only means of preventing the dissemination of the system, whenever attacks of pain in the eye or with some of the unsatisfactory state of the disease.—(*P. 402*.) When the disease shifts to various eyes one eye to the other, and long lasting discharges, Dr. Vesali recommends tapping, and the eye to be again carefully treated by the injection of tepid water or any gentle

stringent lotion; and afterward wiped dry. When the discharge continues and swelling in these stages is to be applied to the shape of the work and behind the ears. He wishes it to be distinctly kept in mind, that the time for the employment of bleeding, with the view of saving the eye, is during the first stage, or early part of the second; and when abatement of the common line commenced, the time is to be treated on the principles applicable to chronic inflammation.

With regard to the plan of discharging inflammatory action by medicines which excite nausea and sickness, instead of having recourse to the vomit, Dr. Vesali states, that he seldom if does not answer well, and to the end purges more debilitating.

As soon as the external motion of the eyelids subsides, and they begin to be exerted, Dr. Vesali resumes the granulations and general eversion, by a very light and careful application of the argentine solution. The eversion portion is then to be continued, and as long as it is useful with a compress and bandage. The method is to be repeated every time the eye is closed, and in the course of a fortnight the tendency to suppuration will be removed.—(*P. 399*.)

As a last resort, vesication, or caustic application, and even more harmful. He first dipped his fingers, and then introduced into their tips a few drops of a solution of the lapis diversus (see *Lancet* 1802), to which was sometimes added a small quantity of the essence of lead. He speaks liberally of leeches, and sometimes he put a small Venus on the temple or behind the ear.—(*See Mackenzie's Ophthalmia*, Milano, 1802.)

Perhaps the best mode of putting an immediate stop to the Egyptian ophthalmia, when it prevails extensively in a regiment in garrison or barracks, is to put the men actually affected into a detached hospital in a considerable distance from the rest of the camp, which should be dispersed as much as possible in woods, hills, and villages. Egyptian ophthalmia is a disease which makes great progress only when large numbers of persons are either exposed together to the epidemic cause, which first, give birth to it, or to the means which occasion the disease to be communicated from one individual to another, as when soldiers are crowded together in the same building, using the same towels and water, &c. Nevertheless the epidemic first and last proved that the disease did not spread in the French army, after the return of several soldiers from Egypt to France, though these were very much with their comrades in hospitals and barracks, the same security did not extend to the British troops of an army of occupation in that country in 1805, who were threatened with a very extensive prevalence of the Egyptian ophthalmia among them, but which was very happily checked by attention to the principles above specified, and in which Sir James Grant, the head of the medical department of that army, had the greatest confidence.

In the cases under Sir P. McGee, local application with fluid extract of stramonium. During the inflammatory stage, however, this granulation also had recourse to antiphlogistic means, such as dry bleeding, venesection, &c. The topical treatment was at first more delicate than freely and repeatedly applied near the eye. For while there was much remaining action, instead of leeches, which caused too much irritation, fumigations with a weak decoction of poppy heads, and a little laudanum, were used. A weak solution of acetate of lead and sulphate of zinc had the most good effect when applied to the eye. The worst features of opinion did not answer the expectations contained in it. But of all the remedies, the best remedy, which was found most frequently successful, it was suggested by means of a caustic of potash, and was first weakened with twice its quantity of lead. The red precipitate, well levigated, and mixed with equal weight, sometimes answered when the arg. being refused, failed. Well-diluted verdigris, and a weak medicine called the golden standard, proved also some success.—(*P. 41-42*.) According to Sir P. McGee, history behind the ears, and upon the neck are useful; but harmful when put near to the eye. In cases where the disease seems to meet with some success, and absorption has commenced on the external surface of the cornea, this granulation appears of the clearing the operation frequent by a posture, as alluded by Mr. Waddington.

When the violence of the inflammation has subsided, Mr. P. McGregor recommends the use of Bates's mucous-eyed water, diluted with five, ten, or sixteen times its quantity of water. But the strongest collyrium, from which he can most good derived, was a solution of the viride of silver, in the proportion of half a grain to every ounce of distilled water. In some cases it may be used stronger.

Tepid water sometimes proved serviceable in removing the action of the complaint.—(P. 26, 47.)

Paralysed Oculobility of Infants. Dr. Vetch describes the external appearances of this case as not materially different from those of the paralysed oculobility of adults, but he states, that its nature is considerably modified by the more delicate texture and greater vascularity of the parts affected; and the more intimate connection subsisting between the vessels of the conjunctiva and those of the sclerotic coat. Hence, he says, the inflammation is sooner comprehended in this case, and sleeping and blinking of the eyelids occur earlier in infants than adults. When the disease ceases, the inner surface of the palpebra becomes anastomosing, and this diseased surface, when the eyelids are opened, forms an extensive fleshy tract, beyond which the relaxed conjunctiva of the eye cannot be retracted as a second; and often the externally fleshy folds add still farther to the valvular appearance which the part presents.—(On Diseases of the Eye, p. 226—228.)

According to the late Mr. Ware, the principal difference between the paralysed oculobility of infants and that in adults, consists in the difference of the tunica conjunctiva: in the former, externalizing the quantity of water contained within the eyelids is often profuse, the inflammation of the conjunctiva is rarely considerable, and whenever the tumor becomes impaired, it is rather owing to the lodgment of such matter as is thus in inflammation; a statement which appears to me very questionable. But in the paralysed oculobility of adults, the discharge is always accompanied with a violent inflammation, and generally with a hæmorrhagic of the conjunctiva, by which its membranous appearance is destroyed, and the cornea is made to come in contact with the eyeball.—(Ware on Ophthalmia, p. 25.) In children, the effect of the eye is considerably accompanied with symptoms on the nose, and with marks of a scrofulous constitution.—(See Ware, p. 138, &c.) The only inference to be drawn from this fact is, that scrofulous as well as other children are liable to this disorder of the eye.

The following is the treatment recommended by Mr. Ware. If the disease be in its first stage, the temporal arteries are to be opened, or leeches applied to the temples, or neighbourhood of the eyelids, and a blister put on the top of the head as temples. The child should be kept in a cool room, not covered with much clothes, and, if no discharges prevail, a little starch or amaranth in spray of water should be prescribed.

A surgical, however, is seldom called in before the first inflammatory stage has ceased, and an immense discharge of matter from the eye has commenced. Of course, says Mr. Ware, no violent applications must generally not be used. On the contrary, anastomosing and coarctate are less readily indicated, in order to induce in the vessels of the conjunctiva and eyelids their original tone, to rectify the relaxed and flaccid appearance of the lining of the palpebra, and thus finally to check the morbid secretion of matter. For this purpose, Mr. Ware strongly recommends the open conopsea of Bates's Dispensary: B. Caput scutellæ, balsam. 32 grs. Camphor 21 M. & F. pulvis de aqua rosæ 3j. in aqua bullientis 3ij. anate ad usum, et instillat foveat. Mr. Ware, in his late Remarks on Paralysed Oculobility, 1835, observes, that he usually directs the aqua camphorata, as follows: B. Caput scutellæ, bals. anser. 4 & gr. viij. Camphor 3j. q. Miso, in affund aqua bullientis 2viij. Clav. levis in frigida, effusula bullientis li q. v. et superadd. pulvis piceus lior anseris et pulvis. This remedy possesses a very styptic quality; but, as directed in Bates's Dispensary, it is much less strong for use before it is diluted; and the degree of its styptic must always be determined by the peculiar circumstances of each case. Mr. Ware restores consciousness about one drachm of it to be mixed with an ounce of cold clear water, in a medium or standard,

to be strengthened or weakened as occasion may require.—(P. 163.) The remedy soon be applied by means of a small ivory or pewee syringe, the end of which is a blunt pointed cone. The extremity of this instrument is to be passed between the edges of the eyelids in such a manner that the medicated aqueous may be carried over the whole surface of the eye. Thus the water will be entirely washed away, and most of the styptic qualities left behind to anastomose and diminish the excessive discharge. According to the existence of matter, and the rigidity with which is associated, the strength of the applications, and the frequency of repeating it, must be regulated. In mild recent cases the lotion may be used clear or twice a day, and rather weaker than the above proportions; but, in inveterate cases, it is necessary to apply it once or twice every hour, and to increase its styptic power as progress; and when the conjunctiva is somewhat relaxed, the strength of the lotion may be increased, and its application be less frequent.

The reason for a frequent repetition of the lotion just considered, is, that when, the discharge, of the most singular nature. Until the conjunctiva is somewhat dried, and the quantity of the discharge diminished, it is impossible to know in what state the eye is; whether it is more or less injured, totally lost, or capable of any relief. The continuance of a solution of the sight frequently depends on the space of a few hours: nor can we be relieved from the greatest uncertainty, in these respects, until the patient becomes visible.—(Ware, p. 145.)

This author recommends the use of emollient ointments, which must have a tendency to increase the softening and relaxation of the conjunctiva. It perhaps not perfectly, he particularly recommends such as possess a thick or cold and lax property; as an extract of the bark of milk, mixed with olive oil, and an equal part of aqueous solution, or an aqueous powder. This is to be put on cold, and frequently renewed, without omitting the use of the injection.—(Ware, p. 145.)

When the eyelids are adherent together, that they cannot be spread after being washed by any length of time, the adhesive matter must be softened with a little rose water mixed with warm milk, or by means of any other soft emollient liquor, after the practice is taken off, and before using the lotion.—(P. 145.)

If the eyelids of the eyelids only occur when the child does, and then goes off, nothing need be done in addition to the above means. When, however, the eyelids are swollen, the injection must be repeated more frequently than in other cases; the eyelids put in their natural position after its use; and an attendance directed to hold on them with his finger, for some length of time, a compress dipped in the diluted aqueous camphorata.—(P. 146.)

In some cases, when the inside of the eyelids has been very much inflamed, the tunica thickens, increased between the eye and eyelids, has been useful. If, after the eyelids are washed, any part of the cornea should be opaque, the anastomosing, hydrant, or mixed, mixed in a spoon, and applied repeatedly on the spot with a fine hair-pencil, or Jones's ophthalmic cement, broiled and used in the same manner, may produce a cure, if the opacity be not too deep a kind. When the local disease seems to be kept up by a bad habit, attention should be directed, particularly the black sulphur of mercury, or small doses of calomel.

The treatment recommended by Dr. Vetch is as follows: if the inflammation have not extended to the conjunctiva of the eye, its further progress may be checked by covering the surface to a healthy appearance, and washing the eye with any mild collyrium. Leeches are recommended throughout the whole course of the complaint. On the first accession of the inflammation, the best effect will often be produced by the application of a small portion of anemone, composed of half or better 2vi, and a gr. of the red vitals of mercury, without any water. As the disease advances, the liquor should be changed, he says, with the following: less anastomosing than in other instances of paralysed oculobility. For preventing the separation of any strength, he recommends a solution of the vitals of silver, and for curing the relaxed state of the conjunctiva, a solution of alum, or of the sulphate of copper.—(On Diseases of the Eye, p. 235.)

The *pusillit opthalmia*, arising either from repression of gonorrhoea, or from the undetected escape of gonorrhoeal matter to the eye, is said to produce rather a swelling of the conjunctiva than of the eyeball, which is followed by a discharge of a yellow gonorrhoeal matter, similar to that of clap. The heat and pain in the eye are considerable, an increase in light occurs, and in some instances, an appearance of hypopyon is visible in the anterior chamber of the aqueous humor. When the conjunctiva proceeds from the second cause, it is described as being less active than when it arises from the first. However, by such distinctions (Parr, *Treatise*, &c.) as have been suggested, instances of pusillit opthalmia excited in the second way, the disease is said to be remarkable for its degree and intensity. The rarity of cases of pusillit opthalmia from the application of gonorrhoeal matter to the eye, seems supported by such a mass of evidence, that I believe the fact must be admitted. Yet, from comments recently published by Dr. Vesich, it would appear, that the frequency of this mode of infection must be very much lowered by the circumstance of the matter taken from the urethra not being capable of communicating the disease to the eye of the individual by whom such matter is secreted, though probably capable of doing so in the eye of another person.

In the next way the urethra cannot be affected by the application of matter taken from the pusillit eyes of the individual in whom the suppurative is made. At least, of these circumstances there is a negative proof in some facts recorded by Dr. Vesich. "In the case of a soldier, received in a very advanced stage of the Egyptian ophthalmia, in whose destruction of the cornea had to a certain extent taken place, I had occasion to represent the possibility of diverting the disease from the eye to the urethra, by applying the discharge to the latter surface. Accordingly, some of the matter taken from the eye was freely applied to the urethra of the soldier. No effect followed this trial which was repeated in some other patients, all laboring under the most violent state of the Egyptian disease, and in all the application was perfectly innocuous. But in another case, where the matter was taken from the eye of one man laboring under putrid catarrhes, and applied to the urethra of another, the pusillit inflammation of the urethra commenced in 20 hours after ward, and because a very severe attack of gonorrhoea. From the result of these cases (says Dr. Vesich) I could no longer admit the possibility of infection being conveyed to the eye from the gonorrhoeal discharge of the same person. Some time after this, the impossibility, or rather impossibility, of this effect was rendered decisive by an hospital assistant, who conveyed the matter of gonorrhoea to himself, without any affection of the conjunctiva being the consequence."—(*New Phil. or Dictionary of the Eye*, p. 242). Hence, this gentleman is led to refer the connection between gonorrhoea and ophthalmia on the same person, to possibility of contamination; but the disease on which this opinion rests, by limits will not allow me to elaborate.

If it be actually true, in adults, a species of pusillit opthalmia does originate from the sudden suppression of gonorrhoea, are we to consider the complaint so profound as a metastasis of the disease from the urethra to the eye? This opthalmia does not regularly follow the suppression of gonorrhoea, nay, it is even a rare occurrence; also, when it is decidedly known that the pusillit opthalmia has arisen from the infection of gonorrhoea, scarcely, in those instances in which the matter has been minutely examined in the eye, it appears that such an affection of the same nature, so produced, is different from the one already so known to it in manner as its progress, and less distressing in its aspect. When the eye is affected, the disease of the urethra is not always suppurative.—(*New Phil. or Dictionary of the Eye*, p. 238). Hence, there is great reason for supposing that the metastasis takes place in this species of pusillit opthalmia, supposed to be connected with a suppressed gonorrhoea; but we must be content with saying that, if it really has such a source, a distinction from a sympathy prevailing between the urethra and eye; and that the difference of intensity in different people, is the reason why it is not an inevitable consequence of the sudden stopped of gonorrhoea.

The injection of water into the conjunctiva of a foreign into the urethra, and the application of some plasters to the perineum, with a view of inducing the discharge from the urethra, form the essence of the practice of those who place benefit where it is the suggestion of gonorrhoea being the cause of the complaint. The rarity of the occurrence, the frequency of the violent emission of the urethral discharge, the possibility of an opthalmia arising as well in and from, these means as in any other, finally independent of the other complaint, cannot fail to raise in a convincing mind a degree of doubt concerning the validity of the assigned cause. Besides, admitting they still is a sympathy between the urethra and eye, how can we be certain whether the suppression of gonorrhoea, be the cause or the effect of the opthalmia, supposing that the one causes, and the other commences about the same time? Attributed by such authorities, I am inclined to distrust symptoms from adopting any means calculated to remove a discharge of matter from the urethra. When the pusillit opthalmia, is a violent disease, indubitably occasioned by the urethra, and infectious of gonorrhoeal matter, applied artificially to the eye, no one has recommended the summary and improper practice.

The first indication in the treatment of the disease from either cause, is to regulate the violence of the inflammation, and thus limit the destruction of the eye and opacity of the cornea. A copious quantity of blood should be taken away both rapidly and gradually; and leeches should be applied, and leeches applied to the nape of the neck, or temples. The eye must be as often furnished with a decoction of white poppy heads, and washed with repeatedly repeated between the eyelids. To prevent the pain from becoming aggravated during sleep, the opthalmic catarrh should be assuaged on the margin of the lids every night.

When the heat and pain in the eye, and the inflammation, have subsided, when no abundant discharge of pus has commenced; all topical remedies are to be relinquished, and a collarium of any, such as emollient hydrarg., any, must gr. j. used in their place. In some cases, that in the opthalmia originating from the inflammatory constitution of the matter of gonorrhoea to the eye, applications in the form of ointment, such as the em. hydn. and resin's, which might be added the ung. hyd. nitrat., and more than find remedies.

Inflammation of the Eyeball is general. From cases in which the eyeball is at first chiefly affected, I pass to the consideration of inflammation, so terminating in the eyeball itself. As Desmarres, remarkably is only very seldom that the whole of the cornea is more affected with genuine idiopathic inflammation, without any part of its surface being spared. Although this kind of opthalmia is far more frequent than common inflammation of the iris, it is much more rare than the same disorder of the eyeball. For the most part, healthy inflammation of the eyeball has a limited point of origin, from which it spreads, sometimes quickly, sometimes slowly, over the whole eye. During an exceedingly violent, when throbbing pain, affecting not only the eye itself, but extending to all the surrounding parts, the humor of the iris, and within the head, the white of the eye becomes reddened and a watery redness, which, on anterior examination, is found to be seated not only in the conjunctiva of the eyeball, but also in the sclerotic, and to reach it from a very thin vascular network, which, as the ophthalmic probe more and more, assumes the appearance of a web, then, forming all round the eyeball a watery redness prominent fluid, which has a very firm feel, and is as tender, than when applied to the greatest growth, the patient cries out in agony. The consequences of this disease continued to be more and more covered by this increasing swelling of the conjunctiva, and at length only a portion of its cornea remains visible. At the same time, the pupil is very much contracted, the iris is immovable; and though vision is nearly or entirely lost, the patient is scarcely disturbed by day light, or even before the eye. When the iris is naturally grey or blue, it turns greenish, and when brown or black it becomes reddish. Every movement of the eyeball and every effort is suspended, and the whole left from patient as if it were now dead, which, then, after, is to verify the name, because the whole of the eyeball, and

and merely the conjunctiva is enlarged, and to project like a flap of raw flesh farther and farther beyond the edges of the palpebrae, and completely fill every part of the orbit. While the eyelid enlarges, the cornea always loses its transparency, and the inflammation spreads to the eyeball, the lower one at last becoming swollen by the exudate, and first thickening of the parts behind it, and the upper one phlegmorizing the most superficial vessels of phlegmorizing inflammation. The secretion of tears and mucus is now entirely suppressed, and of course the eye becomes very dry. At the very commencement of this violent form of ophthalmia, the conjunctiva is disturbed by a severe attack of inflammatory fever, and terrible symptoms are not infrequently seized with delirium. Here, says Beer, terminates the first stage of this very dangerous disorder.

When the disease is left to itself, suppuration comes on, attended with fever and constant throbbings; the swelling of the sclerotic conjunctiva undergoes a remarkable increase, and assumes a dark red colour at the same time that it becomes softer. The eye becomes irregular, thickening, and when the eye or eyelid is touched, of a burning description. At a certain secretion now begins to take place from the Meibomian glands, the eyelid conjunctiva has a more solid appearance. The upper eyelid has a purple hue, and, on account of the continually increasing size of the eyelid, is pushed further and farther outward. The portion of the sclera, still discernible in the middle of the protruded conjunctiva, acquires a fiery redness, which afterward changes to yellow. The patient feels as oppressive sense of heatiness in the orbit, and a disagreeable kind of confusion all round the eye. At length, the throbbing and tension are so agonizing, that the patient often expresses a wish to have the eyeball extirpated. If an efficient treatment be adopted, the eye now bleeds, and a mixture of water and blood, together with the scanty perspicuous remains of the tears and vitreous humor, is discharged with considerable force in some degree in front of the patient: an occurrence, sometimes mixed with or mixed with. From this moment, the pain all at once subsides into a very moderate feel of burning in the eye, and suppuration goes on until all the texture of the organ is exhausted, the orbit has an empty appearance, and the closed eyelid sink into a cavity. There ends, as Beer observes, the second stage, after which follows a general induration. But he remarks, that the course of the case is quite different when it has been properly treated in its first stage with astringents, or exposed to the ill effects of Muscovy smoke, the discharge of pus, improper diet, immoderate exertion, &c.; for, under the operation of these unfavorable circumstances, the second stage may commence with almost no symptoms marked, every vestige of the vegetation of the eye disappearing, and the parts at length subsiding, while the aqueous humor is retained, and, unless efficient medical aid be promptly given, the patient loses his sight.

With respect to the onset of such an attack of the whole eyelid, as soon by common inflammation is a heavily edged, they resemble of an exceedingly violent suppuration, such as is given by a carpenter, burn, and become either of a mechanical kind, or arise both from a cold and mechanically together: a vulgar theory fully proved by the foregoing cases.

The following are the observations, which Beer delivers on this progress.—While, in the first stage of this inflammation of ophthalmia, the eyelid yet remains, and the eyeball itself is not enlarged, if the patient can be properly taken care of, every hope may be entertained of dispersing the inflammation so far as that, with the exception of a weakness of sight, or longer or shorter inflammation, as it often will be. It is to be observed, however, that under these circumstances the patient should not be too bold in preventing a perfect cure; for the very commencement of any inflammation of the whole system, even when the disease is partly abated, is attended with great pain, and may, in the progress of the disease, be attended with more pain, but only in proportion to the loss of the eye itself being destroyed by the most painful means: and when things turn out worse still, a tolerably tolerable irritation of the eye is necessary. But as soon as the process of drying is begun, the eye, nearly closed, and the eyelid phlegmorized, it will be no wonder if the inflammation can be

resolved so as to preserve the shape of the organ; for the restoration of the eye is entirely out of the question. But besides the irremediable loss of vision, the disorder under these circumstances always produces a greater or less change of the pupil, which, however, has no share in causing the blindness.

In the second stage of the case, of course, the hope of restoring vision is quite past, and if the eyeball is still, and not merely the conjunctiva, has been considerably swelled in the first stage of the case, the chance of preserving the natural shape of the organ is extremely suppressing. But when the eye forces the latter desideratum is impossible. If the first stage should have been so violent as to induce gangrene, the practitioner will have enough to do in preventing sphacelus and death; the danger of which is considerable, on account of the aggregate connection between the eye and parts in the orbit, and the brain and its meninges.

In the first stage, antiphlogistic treatment, in the general sense of the expression, is indicated, and the case is not to be regarded merely as a local disorder. However, with respect to topical bleedings, the surgeon, says Beer, should be more active than in other varieties of ophthalmia, and, after copious venesection, and the use of leeches have produced some relief, the protruded conjunctiva about the cornea should be deeply scarified with a lancet. If in the first stage delirium come on, as it sometimes does during the violence of the inflammatory fever, Beer directs one of the external jugular veins to be opened; or blood might be taken from the temporal artery.

In the second stage of the case, when the re-establishment of vision is quite impossible, and the efforts are to endeavor to keep the eye of a good shape, and quickly break the suppuration, when suchness positions, and particularly those made of apples, are the applications on which Beer bestows his pains. This topical treatment is to be mixed with internal means, as explained in the preceding pages, because the disorder is attended with general disturbance of the constitution. When matter is fully formed, and its evacuation can be distinctly felt, Beer approves of opening the abscess with a lancet: for it is only by this means that the resolution of the eyeball can be prevented. If the eye has already burst, the preservation of its form is no longer possible, and according to Beer, both the topical and general treatment should be guided by its state of resolution. When gangrene is formed, the practice ought to conform to the principles explained in the article Mortification.

External Ophthalmia. Inflammation of the Outer Coat of the Eye. *Ophthalmia externa superficialis*, of Beer. The inflammation of this common species of ophthalmia, as the name implies, occurs, has a variety of names applied to it, as, *ophthalmia levis*, *ophthalmia angularis*, *serena*, and sometimes *chronica*, and *ophthalmia rosea*. Together with a partial dryness of the eye, and a secretion as if the eyelid were compressed on every side, the white of the eye becomes covered with a general redness, which, though it affects both the sclerotic and the conjunctiva, will be found on attentive examination to be much more considerable in the former than the latter system, in which only a delicate point of inflammation is at first perceptible. The motion of the eye and eyelid are not remarkably prevented; yet the patient never moves these parts, except when he is actually obliged to do so, on every motion of them, if not actually painful, produces a good deal of uneasiness. Though the lower eyelid be not so loose, as the upper, its clearness is always much diminished; and this change in the position of the eyelids of the eye appears. These effects, which occur almost simultaneously, are followed by pain, which increases every moment, at first extending over the whole eyeball, and then to the surrounding parts, and to the top of the head. As the pain grows more severe, every movement of the eyelid and palpebra becomes more distressing; the dryness of the eye increases, and the relaxation of the sclerotic conjunctiva appears either more slowly or quickly, according to the degree of inflammation, until the network of blood vessels, which was at first distinguishable, gradually disappears and the conjunctiva forms a mass of red clots, quite concealing the sclerotic, and forming round the cornea a very painful, firm, and thick, opaque projection. Thus the cornea seems as if it lay in

a depression, with its margin partly covered by this inflammatory swelling of the conjunctiva. At the period when the proliferation of the latter membrane takes place, the cornea itself always becomes less and less clear, and of a milky gray colour, so that neither the iris nor the pupil can be any longer distinguished, and the power of vision is reduced to a faint perception of light. The pain, which was that of laceration and tearing, now becomes of a throbbing description, and the eyelids, which were before in part taken up in the efforts of the inflammation, are no longer capable of contracting properly the eyelid conjunctiva. The eyelid and eyelids are perfectly insensitive; and if it attempts to move by the patient's own efforts, the efforts of the muscles may be perceived, but still no movement of the parts intended is performed. The cornea looks as if it were too much for the eye, and the inflammation inflicts a severe attack of inflammatory fever. Thus, says Rees, does the first stage of phlogosis of the eye gradually rise to its highest degree, to which he applies the name of *pan ophthalmia*.

However, it is observed, that suppurative external ophthalmia does not always become so violent; on the contrary, when the complaint has been excited merely by the lodgment of some small foreign body under the eyelid; by touch, in such a case, the conjunctiva and cornea are both relaxed together, yet even when much is affected, if no other sources of greater irritation intervene, the inflamed does not readily increase so as quite to conceal the cornea, or to be attended with an extraordinary swelling of the eyelids. This milder form of external ophthalmia has sometimes received the name of *serena*. It is the mild state of ophthalmia of Scarpa, characterized, as this author says, by redness of the conjunctiva and lining of the eyelids, an unusual sensation of heat in the eyes, itching, itching, and itching pain, as if sand were lodged between the eye and eyelids. At the place where the pain seems most severe, Scarpa remarks, that some blood-vessels appear more prominent and larger than other vessels of the same class. The patient keeps his eyelids closed, he is full of weeping and sobbing in speaking them, and by this means he also moderates the action of the eye, so that he cannot expose himself without increasing the burning sensation, increasing pain, and effusion of tears. If the constitution is tranquil, the pain will be a little alleviated, particularly towards the evening; the skin dry; and sometimes slight shiverings and nausea and sickness take place.

According to Scarpa, mild acute ophthalmia is often the consequence of a cold, in which the eyes, as well as the primary cavities, fauces, and trachea, are affected. It is not infrequently occasioned by changes of weather, and sometimes arises from cold to cold, the prevalence of easterly winds, passing through damp, alkaliating, muddy countries, in the hot season of the year, exposure of the eyes to the cold rays of the sun, draughts of cold air, dust, &c. Hence, it does not come extraordinary that it should often make its appearance in an epidemic, and affect persons of every age and sex. As additions to the list of remote causes, authors enumerate the suppression of some habitual excretion, as bleeding from the nose, or puer, the venesection, &c. a disordered state of the primæ viæ, worms, dentition, &c.

Between *serena* and more law writers, there is still some point of difference in their descriptions of external ophthalmia, or else they name different cases; for while Rees represents the redness as affecting the sclerotic or first more than the conjunctiva, other writers describe the affection of the sclerotic as generally second, or even it happens or all, the according to modern observation. It is not unaccountably often an epidemic form of an effusion simple inflammation of the conjunctiva.

At the second stage of external ophthalmia comes on, the symptoms are something in the degree of the complaint in its first stage, but when, what Rees calls a true *chemosis* is produced, the following are described by him as the usual appearances. The circular prominent fold of the conjunctiva round the cornea becomes of a dark red colour and the swelling increases, but it becomes softer and less painful. The hardly visible portion of the cornea, situated in the depression formed by the circular protuberance of the conjunctiva, seems at first perfectly white, and afterward yellowish, being

the seat of more or less purulent matter. Though the second conjunctiva is every where increased, still a thin white membrane, this secretion, says Rees, is very so copious as to run over the face, at the third stage of the disease. In the early of the first stage is noticed considerable effusions, in consequence of its being becoming more evident. While suppuration is taking place in the system attended with the whole conjunctiva which usually accompany the symptoms of acute ophthalmia, little collections of matter sometimes occur at different parts of the conjunctiva, and also they have hard, a probe may easily be pushed under deeply into them without any painful pain. (P. 1, p. 412.) The suppuration continually increasing, the swelling of the conjunctiva, and of the whole eye ball, now diminishes, the effects of the inflammation penetrate deeply into the cornea, and the cornea of the eye is so altered as not to be recognisable, the part whitening up, as Rees says, into a substance which is hard. However, sometimes in the early stage deep effects of suppuration are sometimes produced only in a certain part of the eyelid, especially when the situation is the conjunctiva, or in the external injury; and in the meantime the rest of the conjunctiva of the globe of the eye retains its natural organization, while in the part above stated there is a funnel-like depression, attended with a considerable discharge in the case of the eye.

But, says Rees, when an idiopathic external inflammation of the eye has only attained the third degree expressed by the term *serena*, he, he knows, that the complaint is principally owing to the influence of some extrinsically or internally existing substance under the eyelid, the nature of the conjunctiva and sclerotic substance a remarkable increase in the amount of the second stage the first of that stage becomes more or less marked; the eye is not much enlarged, and the conjunctiva is more or less inflamed; but at the point where the extrinsic substance lodged, an open superficial suppuration occurs, and, according to Rees, the case, both in the first and second stage, is generally accompanied with no other symptoms.

In the first stage, Rees represents the progress to be very disagreeable, provided the disease does not extend that degree to which the name of *serena* is applied, for with the aid of proper treatment the inflammation, when of a healthy kind, may be soon and successfully removed, as not to leave a vestige of a mark. If the cause of the disease be not given that a permanent injury or wound of the eye, the inflammation of the whole eye, perhaps, will remain, but stoppage, as does in the inflammation *serena*. In the other hand, when this kind of ophthalmia presents itself in the form of true *chemosis*, the prognosis is seldom and the worst is made with great safety, especially when the patient is of a weak irritable constitution. A third very common and unaccountable, or a variety of following strictly the advice which the constitution has actually afforded; for under these circumstances it will not be in the power of the doctor to prevent the inflammation decreasing spontaneously in its second stage, so that even the inflammation of suppuration will be incalculable. But if these inflammatory conditions are not present though the present symptoms are not present, they may have caused a vision and when in its highest degree in the first stage, and that the eye may be saved by proper and judicious treatment, but also the opposite; one will the most be difficult cure when the cornea continues for some time destroyed by transparency, and the power of vision impaired to a slight various affection of the conjunctiva remains. These effects, says Rees, at length, somewhat frequently, how in consequence of the aid of modern medicine, a proper regimen, the patients and even some of the best do not die.

The progress in the second stage, is under very different circumstances; for, as Rees observes, though the inflammation in the first stage may remain without that degree which is implied by the term *serena*, yet if any irritating point succeeded by some, with the possibility may be not efficiently treated, it will be very likely of substance already produced by the injury itself, a more or less suppurative white excretion will remain on the cornea, and cause a permanent impediment to vision in a degree depending on the situation and extent of the opacity. And in addition to the

1906, it is to be remembered, that if the corresponding points—strictly understood, or extremely nearly so—of various or numerous parts be penetrated by a substance, and, in the first case, a prototype of the life or pattern of the system in the current (organic whole), a disengagement in the past, or an irregularity of the system, be produced; which, in the second, the disengagements may be a partial wandering away of the system, attended with loss of sight and of the natural shape of the part.—*Ibid.*, p. 176, 871.)

These lamellar structures, that when this species of a polychaete larva is still in its first stage as the *Stomatopoda* larva, are the beginning of the second stage in early metamorphosis. For when the *Stomatopoda* is eventually transformed by superaddition, the apophysis and its lamellae acquire the form of the coracoid, and for the first time, and in the beginning of the time can be observed a connection with the main lamellae of the coracoid. But when the middle portion of the lamellae is cut off by the connective, toward the apophysis, the idea of a possible change in the evolutionary history of the superaddition, of an idea of the origin of the apophysis, and the lamellae, will be very successful if he can find evidence to indicate that the migration, which corresponds with a great deal of physical adaptation. An extraordinary relationship of the connective of the lower coracoid and a posterior coracoid are the two main distinctive effects of the migration of the eye, but produced. Lastly, they indicate that the changes in the lamellae of the eye, that is to say, the changes in the superaddition of the eye, is easily explained, that the most remarkable consequences, that the apophysis and origin of the apophysis are produced entirely due from metamorphosis.

—(P. 1, p. 108)

As a result, we conclude that the treatment of idiopathic severe optic atrophy as a modification of aqueous humor formation, of the neovascular, mild acute optic atrophy as a steroid, and severe acute optic atrophy with steroids.

According to Mr. Tracey's simple refraction of the cornea, and without effecting what injury of the eye, and without depending upon any extended disorder of the system, not assisted by a morbid diathesis, may be easily and speedily relieved, even to its most acute form, by bleeding, and more brisk doses of mercury mercurial ointment, or *Unguentum of the Dispensary of the Disp.* 2, 361. In the case of cold acute ophthalmia, foreign, irritable low light, gentle purgative, foreign mercurial low light, gentle purgative, with mild repeated doses of mercurial ointment, the removal of any extraneous body lodged under the eyelid, and frequently washing the eye with warm decoctions of mulberry-leaves, and rubbing with a very mild pomatous ointment, directed to a free state of the eye. Mr. Tracey also expresses his decided preference to a dry application to the partially acute state of inflammation, and considers it more useful when generally better than indicated, than the aqueous solution of opium, or infusion of poppy seed extract.

When the disease proceeds itself to its first stage, in the cold state of tissues, says Barz, it usually terminates with an erysipelas, accompanied with an enormous suppuration, and may be cured by energetic antiseptic treatment, in which, indeed, since the system itself is affected, particular attention must be paid to lowering the action of the liver and all upon the organ. But when a true diphtheria is present, every antiseptic remedy must be promptly and vigorously put in practice, internal as well as external, remedies being employed, and besides disease treatment, the physicians, would the system it to be disturbed, a proceeding never necessary in the case of diphtheria. Such considerations, Barz observes, have a wonderful effect upon patients, practiced in the proper period, after consumption and rapid healing with little have been fully put in operation, and when the case is under way, as in a profuse immediately a profuse discharge of blood.

"By the action of such antiseptics (says he) I have cured the inflammation and all the threatening effects, such as it were, which may have, when an initial cold state is followed by other symptoms."—(6, 1, 2, 188.)

In this country, the best practitioners rarely make mistake either in nature of the condition or treatment, and have more confidence in general than local treatment.—(Walton; *Notes Pract. Med.* of the Brit. M. S. 2.)

ON the application of the experiment of ether, or of the
Yon. II.—Q.

points of reference to the eye and eyelids. So the relief is dramatic, as recounted by Mr. Ware (p. 54). I shall say why this eye surgery with all its risks merits the appreciation of such first-hand witnesses.

Manuscript has been received, having taken a part in the first stage of the work, by manufacturing negatives of the original dissections, and after the positive printing is done, according to the directions given in a copy of this article. In the first stage of several acute ophthalmias, *Serpula* resembles the glass (solid) applications to the eye seen in *Conio* and in *Indur* (noted in next article), but is not as hard as the latter, and is a much lighter color. It is made to distribute human hair. Careless of this treatment should be repeated at least every two weeks. The patient should be directed to consume, before going to bed, and to go with his head in an elevated position. In the case of a child, sitting up in the night, the application is proper. When ophthalmia is accompanied with a violent pain in the head, the hair *Man* is indicated, a strong decoction of *pepp* made as a preparation.—P. 51.

[illegible]

Widely distributed, the good effect emphasized in the second series of experiments by the application to the tip of the beak of groups of the vibro-motor of 14 Hz, much or twice, a day; a subject already examined in the first series of experiments. The quality of feeling of eye is indicated in the last column as being best in most cases; it is indicated, a case of great improvement, that no further improvement, but here, doubt, because that have already resulted upon the general observations.

When idiopathic myofascial dystrophy has increased a supposition of little value. Beebe speaks largely of the strength derived from a section of the lips down to (see *Leontopitium Dugesi*), considering the larger vessels of the vessels, as first stating the supposition, but with a full illustration. In some cases, Beebe says, that when such local treatment is combined with the liberal exhibition of boric acid and mercury, and diet and regimen conducive to the support of the nervous system is very great. And here, again, it is worth observing, that while the strength of the jaw muscles is of great service in the several stages of the disease, it is more of the importance in the kind of disease which antithesis (purulent) epithelioma, especially if not blooded with mercury, and even when these combined, it cannot be entirely by weak and unstable subjects, affected with the latter complaint; it is not observed in other instances of disease. (*B. v. 481*).

When particles or elements in the applied conjugate pass around the column, a free radical on the matrix can be immediately made inactive if there is a suitable site for it to be set down, as Berc and others, in the next mill second extensively, and the crystal will be in danger of being destroyed. For this reason if the method involving the oxidation of the lower crystals, somewhat resembles as a consequence of the direction, see

information of the situation. The results, except in cases of bilateral, according to the degree of the eye first or directly affected, patients, I think, to be clearer views of the subject, and perhaps gain. One circumstance particularly observed is both

words in nearly straight lines from the posterior part of the eyelid, and extending along the inner side of the tarsal opening, passing over it, not far from the pale circle around it, which is so seldom when either the closed or the eye is affected. When the vesicle is closely examined, the general impression is of hard polished ivory by numerous small ramifications upon a few large trunks. There is *temporarily* a little swelling of the conjunctiva which sometimes forms a slight but constant ring round the tarsus. In most cases, little change takes place in the affected conjunctiva in the early stage, but in the chronic affections the cornea becomes thick and cloudy. Upon these eruptions, crusts form of the nature of the crusts found on the cornea, but generally to be found on hardened, especially on scars in the cornea. At the commencement of the disease there is often a temporary burning or dryness of the eye, but none of these very severe sensations of itching follow. The eyelids are increased in size very little affected. About the first stage of pain is generally the least, though sometimes, in the earliest stage. Mr. Wenzel describes conjunctivitis usually most severe in the angle of the affected eye, but he says that it is often noted in the lips, the cheek-bone, the teeth, or the lower jaw. — Sometimes the pain is peculiarly confined to one-half of the head, and sometimes there is a severe pain in the cavity of the nose, or in the ear. The pain is often of a dull agonizing kind when alone, and though increasing they vary much in degree, though as it takes in very severe paroxysms, and with great violence when the head is bent downwards. Sometimes the pain is excited by touch, by raising the eye and the patient is unable to rest his head on the affected side or eye, as it is a pillow. In some cases the pain is said to be constant, the patient being so in the evening, continuing during the night, being much worse about midnight, and abating towards morning.

In his system, says Mr. Warder, the patient gradually discharges more of a series of false and dangerous than of pure; and though there is a predominance of cerebral action, the eye does not seem to suffer from excessive light, as in certain forms of disease. The patient is directly opposite to him, at least, in relation to the first stage of the disease. However, these notions, which are in considering the after-effects of generally the chief seat of morbid influences; but these are down the eye as the chief subject to be considered. He admits, according to the second stage, the system is light and even a considerable degree of it. According to Mr. Warder, the morbid condition is always accompanied with more or less sympathetic fever, the paroxysms of which take place through the eye, and the function of the latter is somewhat deranged, the eye being irritated, and the secretion of tears continued in quality. In second stage, the part in the head seems to be more sensitive; the relation of the system increases, the whole white of the eye is covered with blood-vessels, and the conjunctiva is red. At high elevations, sometimes in the nose, through which the aqueous humor is discharged, and the eyelid contracts, when the pain ceases or diminishes, may find within the posterior chamber and even through the sclerotic coat.—Warder, in *Med. Obs. Trans.*, vol. 10. "Two females could not see, owing to the number or white of the vessels existing during severe pain (as) such cases were known to be symptomatic of a small-pox, but both out of the course of the disease. He adds, that they were both very old, and that generally in old persons, the disease is usually subject to the fallacy of the eye, and not of the eye."

The criticism that the oculist's examination was too superficial, was a charge of ignorance, void of any basis in fact, and a gross misstatement of the facts. The oculist's examination was a complete one, and the only one that could be made at the time. The oculist's examination was a complete one, and the only one that could be made at the time.

According to Mr. Waring, this kind of pathology resembles syphilis more than any other kind of inflammation of the eye. There is nothing that is fundamentally different in the general course of the disease com-

enlarged, which is the cause of the redness being generally defined over the whole abdomen, whereas in epidemic dysentery it is in the extreme sigmoid flexure passing along the abdominal wall; they may be the same, which are chiefly applied, and hence the pain may which is always observed between the rectum and the enlarged vessels. Mr. Winslow further explains, that though these diseases resemble each other in the point toward the point, and have various treatments, a strict look at epidemic dysentery always has the constitutional symptoms of dysentery.

When the woman has made much progress, and the symptoms have not yet yielded to more resolute, Mr. Warfield recommends the operation of the syngonium, known as a practice taken up with the most beautiful effect in my development. After the operation, however, it is the only remedy applicable; but if the eye cannot bear it, the same nature of opium is to be used. He gives attention to the side of the biliousness in everything after the same, and speaks highly of the water (not water) added to an elastic, each being taken to supply the needs of the system, and the whole, or other patients. If the face of the eye was suddenly interrupted by a chill just before the attack, the author prescribes a couple of grains of arsenical powder, when, in connection with opium, it is taken every four or six hours. The advantage, he says, is derived from local bleeding and where remission may become necessary on account of the continued presence of the disease, it is to be modified with moderation.

In the early stage, Mr. Wadsworth has found, that the parts of the eye and conjunctiva are sometimes much affected by a conjunctivitis with the development of purgery lesions. He also writes: "Many in the time of the neck or behind the ear; but diagnosis of their being put under the eye itself." The various distinct organs, in fact, in the only local application which he has seen with decidedly beneficial, but the use is to be delivered with a fine cloth of the white material, when all definite symptoms have been subdued. "After the intense sore throats have been treated, the conjunctiva still remains very white, and the pulse quicker than natural." As the state, actual dose of bark, water alone or with the mineral acids, will become more acute. — *Wadsworth*, in *Med. Clin. Trans.*, vol. (6). The outline of Bee's practice has been given very briefly, in the final stage, he applies a decoction to the nasal cavity, and covers the eye with a cold pessaire, notice again, properties of similar in the water with which it is made. Disinfectants are also prescribed. In the several stages, galls, cones, sulphur, strick, antiseptics, lotions to the neck; or behind the ears, friction with oil on the conjunctiva, and covering the eyes with loam of aromatic herbs and camphor, are the means of relief. When attacks of conjunctivitis exist on the conjunctiva, sclerotic, or cornea, a collection of the blood vessels, with a large addition of the blood fluid of veins, is contemplated; or if the vessels are large and on the cornea itself, they may be treated with the large incision for veins of a raised size pencil. After each one of the collections, Bee covers the eye again with the type of ointment for the conjunctiva. — *See Billie on Properties of the Eye*, vol. 2, p. 218. Regarding the last application, I have already expressed my belief, that it is the which is not likely to obtain credit among the scientific community.

Staphylococcal ophthalmia. One of the peculiarities of this case is, that it is usually attended with pain. As Dr. Truick observes, the intense fact is very marked with respect to staphylococcal inflammation in the conjunctiva; it is never there characterized by a distinct of vascularity—(see *Opht. of the Eye*, p. 23, of 2.) According to Mr. Truick, when staphylococcal inflammation of the conjunctiva is not attended by change of texture, it is not limited by any particular local character. "The vascularity is inflammatory. This inflammation sometimes accompanies people of the sclerotic conjunctiva, in which case the vascularity is diffuse, instead of being partial as in pure catarrhal inflammation, and the intolerance of light characteristic of the staphylococcal inflammation is present in a greater or less degree. It accompanies, then, the most secretions of the lids when the eyeball becomes affected by the acuteness and duration of that disease, and the principle of the virus, especially the staphylococcal. In its strongest form, it is almost peculiar to young children, and

tion which we are capable of giving, is contrary to accurate ideas of its formidable nature. The attachment of the stomach to the important structure of the neck and shoulder of the left side, and in so great a degree, is sufficient to indicate its importance and difficulty.

The extensive nature of this operation led us to take the precaution of securing the external jugular vein with a double ligature, and dividing it lower on the neck. Though in operating upon the neck we have several ligaments these veins without any important consequences, we however think we have increased almost (and often from the division of a large vein, and the admission of air into the circulation).

The case of James Daggette's, in which a young woman suffered under an operation, from the division of a large vein in the neck, while he was engaged in removing a tumor, contributed, with my own experience, to make me take the precaution of previously tying the vein in this operation.

It was at length decided that to remove the pericardial gland in an enlarged and swollen state, the first step, which it passed over the base of the lower jaw, was opened in dissecting the ligaments from the trachea, at the early stage of the operation, before a single artery was tied. At the instant this vessel was opened, the situation of all present was arrested by the bursting issue of air issuing into some small opening. The breathing of the patient immediately became difficult and labored, the heart beat slowly and irregularly, his features were discolored, and convulsions of the whole body were followed to so great an extent as to make it impossible to keep him on the table. He lay upon the floor in this condition for some half an hour, as all supposed in artificial respiration. As the convulsions gradually subsided, his mouth was permanently distended, and complete hemiplegia remained to have ensued. An issue and more enlarged before he could articulate, and it was nearly a week before he recovered the use of his first and last. From a belief that these effects arose from the admission of air into the blood vessels, which was not detected by any person present, I instantly failed to make a set of experiments which I made some thirty years ago upon dogs, by blowing air into the circulation, by inserting a blow-pipe into a large superficial vein upon the neck, and was finally struck with the similarity of result.

No severe symptoms of a general or local nature took place to interrupt the process of presentation in the trachea. The trachea was cut, and the lower and upper parts as have been described, only occurred with that necessary complication of great solicitude, until a new apparatus fully established and the great vessels covered by tracheotomy.

No difficulty attended moving his shoulder in a proper position by the use of the external apparatus for drawing clays. With this aid he held about a whole day in convulsion, after five weeks elapsed, and two months from the time of the operation, he was able to discontinue his sleep, and by means of an apparatus contrived by Mr. James Rice, a most ingenious and inventive artist, to supply the want of clays, he was as fit as to have his shoulder in its proper position, at the same time that the full motion of his arm was preserved. — (Rice.)

JOVARIAN TUMOR. The following highly important and interesting case, heretofore, perfectly unobserved, is given by Dr. Daniel L. Rogers of Illinois, in a very great practical importance, that I have concluded it would be acceptable to the profession to have the description of the operation and its result inserted verbatim. Very many are actually falling victims to this disease, who might be preserved by a similar operation.

In July, 1829, I was requested to operate on a woman for pericardial tumor; after drawing off the water, I observed that the abdominal tumor was unusually large, upon examination I discovered a large tumor on the left side of the neck, and extending to the left side. Surgery the following history of its origin and growth. Two years since, in her young days, while in this country, after being two weeks at sea, she had a supposition of the catarrhs, which was soon followed by a sharp lancinating pain in the left hand region, provided in winter, her health had always been good. On finding the pain increased, and the abdomen began

to swell; first on the left, and then extending to the right; the stomach became affected, and although unattended, her stomach acquired her of being purgative.

In consequence of this oppression, the disease was allowed to proceed without any medical advice, until time had extended her fluids in the cavity, when a physician was called, who pronounced the disease a dropsy, and recommended first to be bled.

A large quantity of water was drawn off, but in two months it had accumulated, and the oppression was repeated five times previous to my seeing her. It is supposed that within the two years, sixteen gallons of fluid were drawn off.

I observed in this case, what I have remarked in several others, that the fluid discharged differed from the water in other cases. It is much more transparent; of the consistency of honey; of a milky color, and differs from any other secretion that I am acquainted with. After deliberately examining the tumor, and as for the possibility of its being cured by its operation, at the same time stated the great risk of its attending the performance, and the probability of its recovery. I likewise expressed Professor Hall, who was consulted in this case, to make a similar statement. His good constitution and general health at this stage of the operation, led me to attempt a cure. After the incision, nothing could be done but determination to keep the chest of water which even so desirable an operation might afford, and to the expression, "I would rather die than live in my present condition."

On the 10th of September, she was laid on a table of convenient length, and with a large vessel I commenced making a hole in the pericardial space, carrying it parallel with the trachea, and presenting an oblique position. The pericardium being divided, the fluid was evacuated through the touch of the hand after to the pericardium. This was at first supposed to be much (perhaps, better) a cautious dissection through a membrane in nature to the depth of a quarter of an inch, the water passed out with considerable force. With a pre-dissected lancet, the opening was enlarged in the first part of the external incision, and to our surprise we found that a set was now opened which appeared to be the whole circumference of the abdomen, and at first its attachment appeared enormous, and with it was. It lay in connection with the liver, stomach, spleen, and bladder. By pulling up the set it was found that the adhesions were much looser at first exposed. It was determined, therefore, to detach them from the pericardium and omentum: some of the adhesions were so slight as to be separated by the finger, others by the handle of the scalpel, but the greater part required to be separated by a tedious dissection, and in some parts the adhesions were so close that portions of the pericardial membrane were removed. These adhesions extended for three or four inches around the abdomen. After completing this part of the dissection, the tumor was drawn out and supported by an assistant, and the dissection continued: separating it from the omentum, which required much care, from the large and numerous vessels going to it from this source: the tumor was at least the size of a goose-quill. After occupying two hours in the operation, the huge mass of dropsy was safely removed, and laid on the table. The ligaments were all cut above the knot, and left to absorption. The wound was closed by sutures, dressed with adhesive straps, but, a compress and a bandage applied freely to the abdomen. I place some confidence in the close application of a bandage, as it brings the divided surfaces in contact for the purpose of adhesion, and I believe it is an important auxiliary in preventing inflammation. She was then removed to bed; her state at this time was better, but regular. In the course of the evening, considerable reaction came on, with some heat of skin.

Within fourteen days of the progress of the case, it will be very necessary to add that the case progressed without any untoward symptoms, and in six weeks from the period of the operation her constitution had returned and her health entirely recovered.

The tumor was composed of a large sac, which contained the fluid drawn off in different operations for dropsy. One third of the tumor was solid, con-

present in becoming adherent to the glans. He says he has seen the opening of the prepuce so much contracted, from the inverted skin hanging and swelling, that there was hardly any passage for the water. If the passage in the prepuce, as contracted, be in a direct line with the orifice of the urethra, a bougie must be used. If otherwise, the operation of slitting up, or retracting part of the prepuce, becomes necessary.

When matter is confined inside the prepuce in the manner above described, Mr. Hunter recommends trying the prepuce open from the external orifice to the bottom, where the matter lies, as in a white of onion. However, he thinks the probability of this operation for the mere purpose of applying dressings unnecessary, as the acids may be washed with gentleness by means of a syringe.

I happened to verify my apprehension at St. John's Hospital, at a time when the fashion of calling every phlyosis inflamed or not, was the fashionable; and I had several opportunities of witnessing the irreparable consequences attendant on neglecting these conditions. It gives me pleasure, therefore, to find this villainous practice partly discovered by a modern writer. "It is not so common," says Mr. Treves, "to cut the inflamed prepuce, as it used to be a common part. I lately saw a phlyosis treated by a threatened and rigid state of the membrane of the prepuce during the first two of mercury, consequently with injury, for the use of two weeks, each of the size of a split pea, situated one on each side of the superior fold of the prepuce. It took the system of an enormous suppuration, that thing being, which was thoroughly miserable, would not heal unless the prepuce was freely divided; and separated with the most slow, after positioning for some days, I slit it up. Thereon immediately healed, but the wound so quickly assumed the same hideous and irreparable character which had belonged to the penis, and was now in danger that it would be only a transfer of the disease from one part to another."—(p. 120.) I have not only witnessed this stage, but, in several cases under the late Mr. Hughes, and in St. Bartholomew's Hospital, but have seen no treatment brought on by the still more rash practice of cutting the prepuce, unless when the part was in a state of acute inflammation, or when very acute when it, when the constitution was in a relaxed and very dissipated state from the immoderate and immoderate use of mercury.

The common operation for the cure of phlyosis consists in slitting open the prepuce nearly as whole length in the direction of the penis. This plan is certainly the most eligible when the matter of a phlyosis cannot escape from under the prepuce; leaving continuous, which many surgeons were Mr. Hunter's main line preferred, might not suffice for giving vent to the accumulated pus. In many cases of phlyosis, says Mr. Hunter, an operation is necessary; for while the inflammation is very considerable, such a remote might bring no satisfaction. He acknowledges, however, that there are cases in which a freedom given to the parts would prevent the latter event. When matter is confined under the prepuce, he seems as speaking indisputably; and of the patient should object to the common operation, he advises its opening to be made with a lancet directly through the prepuce, or even with a razor.—See Hunter on the Venereal Disease, p. 352, &c. &c.

When the prepuce is to be slit open, a director is first to be introduced under it, and the division is then to be made with a curved pointed bistoury from within upwards.

Many surgeons object to this operation, because the prepuce contains adherent to a very deranged state, and they prefer circumcision, or excision of the prepuce, in the following manner. The prepuce is first cut off with a pair of forceps, as much of the part being left out as is judged necessary to be removed. The removal is then accomplished by our sweep of the knife, which, directed by the index of the finger, is very of making the incision in a straight and regular manner. A fine silver is next passed through the edges of the lower and upper portions of the divided prepuce, so as to keep them together. The only absorbent dressing is used, and over it a fine dressing.

Dr. Ryan lately mentioned to me a new plan of operating on phlyosis, which is less severe than the common one, attended with no suppuration, and, ac-

cording to this gentleman, very efficient. It consists in drawing back, as far as practicable, the external skin of the prepuce, and then introducing a sponge under to internal epiphyma, and drawing it with a narrow curved bistoury. In some cases, I have no doubt that this method would completely succeed, and remove the surgeon to draw a better name the prepuce, and even to remove the phlyosis without making a cicatrix. The point of M. J. Chappet who merits notice. It consists in cutting the outer surface of the prepuce open to the extent of a line parallel with the foreskin. When this latter part is very short, it is to be divided with the scissors. The incision is made, says this author, because it is more direct than the common one, and scarcely any dressing is necessary.

At the period when I first entered the profession, it was the custom to advise every patient who complained to have a phlyosis. However, now that we are full of any irritation about the prepuce and thus perceive that of common waste, being treated by the plan the complaint is still longer, even the operation has been relinquished, and treatment and caution of the disease are always considered possibly in the determination for any particular method of treatment. Nay, even when phlyosis does not arise during, if there be a great deal of inflammation, the use of mercury may rather do harm than good, and the phlyosis should not be precipitated in its development. On this point I fully coincide with Mr. Treves. "Upon many occasions," says he, "patients are led to suppose to contend with the specific character of the venereal disease, to the neglect of the inflammatory state of the affected parts exhibited above its light. This abuse of administering mercury for such purposes and result, more, accompanied by phlyosis, or an approach to that state, is of common occurrence, and it is far from being recognized by the profession as an established rule of practice, and its continued administration is especially during the existence of active inflammation to exclude mercury."—(Treves's Essay, part 1, p. 121.)

In rare instances of venery, in which the prepuce is not diseased, the patients were also advised with a natural phlyosis.—(Frost, On a Syphilis.) But his notion, the same thing is three times repeated, and as he maintains that phlyosis may be removed by cauterization of the penis, he shifts his ground always in the end.—(Faulkner de la Harpe, English, p. 306.)

TREATMENT OF PARAPHIMOSIS.

The removal of the stricture in this case should always be effected, because its continuance is apt to produce a mortification in the parts between the stricture and the glans. It may be done in two different ways by compressing with the finger at the head of the swollen corn, or at to render this part soft, and then to apply the constriction prepuce to be brought forwards over it with the aid of the two fingers, or by dividing the stricture with a lancet. In a former edition of this work, as Mr. Jones of Philadelphia has remarked, "the power of this operation, in producing the reduction of the prepuce, should have been mentioned. This method should always be put in practice before the reduction by compression is attempted, as a preliminary measure, which sometimes succeeds of itself, and renders unnecessary any violent handling of the parts. First, the prepuce is drawn forward over the head of the penis, behind the prepuce. There are several the first mode, I believe, phlyosis, the second one to be so frequently necessary as Mr. Hunter seems to say. This operation is not so troublesome as is supposed, because the stricture is easily of the entire corpus in close the right part, which change be put it without difficulty. Mr. Hunter says, the best way is to separate the two stricture as much as possible when you push it out, and so expose the constricted part; then take a small pointed bistoury, pass it under the constriction, and divide it. None of the swollen skin on each side should be cut. The prepuce may now be brought forward, where it is brought more extended, for the purpose of drawing the stricture, in which it is the power, phlyosis."—(See Hunter on the Venereal Disease, p. 336, 337.)

The original disease producing phlyosis and pre-

glycogen must always be situated in, and the arrangement of them must be necessary in consequence according to the nature of the affection of which these are the effects.

One of the most interesting studies in physiology and pathology is J. L. Petit, *Traité de Méd. Cas. 12*. *Cronica* also J. Hunter on the *Præternatural Diseases*. *Schæffer, Médecine Hypochondr.* L. J. Nov. 1800. *Diagnose, ou Séméiologie Médicale*, par J. B. Lenoir, 1802. There is also a valuable chapter on this subject in *Hunter's Observations on the Venæ*, p. 6.

PILULE—See Memorabilia.
PILULE ARGENTI NITRATÆ. R. Argenti nitrat. gr. iij. Aquæ distillat. pili. aquosæ. M. S. 1819, p. 10. In first pil. 21. The nature of the Pharmacopœia Composita suggests the trial of these pills in chronic hæmorrhæ and other cutaneous affections, and phlegmatic, as well as dyspepsia associated with constitutional poverty. Two or three may be given twice a day. Dr. Ferri gives the argentea tinctura alternately in cases of hæmorrhæ, but without any sensible effect.

PILULE COLONYSTIBIS CUM HYDRAIL. R. Hydriarg. colonystib. comp. 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These pills operate as a purgative, and they are often prescribed in various chronic cases.

PILULE CUSCÆ. R. Cuscutæ seed 3j. Pulv. betæ, coarsely, 3j. Hydriarg. 3j. These are the best pills in the use of Guy's Hospital. They are occasionally given in catarrhs, cancerous, and venereal cases. The surface should be kept with small doses and increase them gradually till cure, and continue for some time to a greater number of these pills may be given in this manner every day.

PILULE CUSCÆ SULPHATIS. R. Cuscutæ seed 3j. Hydriarg. colonystib. comp. 3j. Saponis 3j. M. In first pil. 21. These pills may be given in a day for chronic—(Pharm. Chirurg.)

PILULE HYDRAEUTÆ. Of these I find only obscure hints, that the first dose is ten grains, per Mercurium, but when prescribed as an alterative, from three to five grains will suffice.

PILULE HYDRAEUTÆ OXYDI RUBRI. One grain of this preparation is each pill in the dose, which is commonly taken at bedtime. (See Mercury.)

PILULE HYDRAEUTÆ CUM CUSCÆ. R. Hydriarg. purificat. 3j. Cuscutæ seed 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. The best alterative is to be first reduced by nitrate with the gum resin, moistened with a little rose-water. The saturated spirit of turpentine is afterwards to be added, and, being the powdered leaves in sufficient quantity to make a suitable size for pills. These, said to slight variation in the proportion of the leaves, are the pills recommended by Ferri, who directs them in five pills, each of three grains, to be given every night and morning.

No doubt there are many cases to which this formula may be very suitable. For instance, the enlarged vesicular gland, and some forms of hæmorrhæ, &c. For such diseases, Dr. Simpson is the Ferri's formula. Dissolve equal parts of pil. hydræutæ and turpentine root. (Pharm. Chirurg.)

PILULE HYDRAEUTÆ RUBRÆ. R. Hydriarg. sublim. gr. xij. Cuscutæ seed 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These are the yellow pills in some cases. Saponis give two or two of these pills, as alterative, in chronic cases. At Guy's Hospital they add three grains of the gum resin to each pill, increasing the dose of the resin.

PILULE HYDRAEUTÆ RUBRÆ CUM CUSCÆ. R. Hydriarg. sublim. gr. xij. Cuscutæ seed 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. One may be given three or four, in some cases, cancerous, scrofulous, and some venereal diseases, preceding several doses.

PILULE HYDRAEUTÆ RUBRÆ CUM ANTIMONIUM TARTARIZATO. R. Hydriarg. sublim. 3j. Antimon. tartarizato. 3j. Saponis 3j. M. In first pil. 21. These pills are given in a day for chronic—(Pharm. Chirurg.)

PILULE HYDRAEUTÆ RUBRÆ COMPOSITÆ. R. Hydriarg. sublim. 3j. Cuscutæ seed 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These pills are given in a day for chronic—(Pharm. Chirurg.)

PILULE OPI. These need only be mentioned among such as are of criminal utility in surgery.

PILULE OPI COMPOSITÆ. R. Opi purificat. 3j. Saponis 3j. Hydriarg. sublim. 3j. M. In first pil. 21. Used for alleviating pain and keeping up a gentle perspiration; are particularly useful in procuring painfulunctions in cases of hæmorrhæ, chronic, &c. (See Phlegma Chir.)

PILULE QUININÆ. R. Quininæ sulphat. 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These pills are given three or four in cases of hæmorrhæ, and in various of the venereal glands from which.

PILULE QUININÆ SULPHATIS. R. Quininæ sulphat. 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These pills are given three or four in cases of hæmorrhæ, and in various of the venereal glands from which.

PILULE QUININÆ SULPHATIS. R. Quininæ sulphat. 3j. Hydriarg. sublim. 3j. Saponis 3j. M. In first pil. 21. These pills are given three or four in cases of hæmorrhæ, and in various of the venereal glands from which.

PLANTARIS MUSCLE. This is the muscle of the foot, which is situated between the heel and the ball of the foot, and is the most powerful of the muscles of the foot. It is the most powerful of the muscles of the foot, and is the most powerful of the muscles of the foot.

POLYPUS. A tumor, generally of a pyramidal shape, most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base. It is most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base.

Polypus is a tumor, generally of a pyramidal shape, most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base. It is most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base.

Polypus is a tumor, generally of a pyramidal shape, most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base. It is most commonly met with in the nose, uterus, vagina, and anus, and arises from a cystic or tubular base.

passing to the throat, or upon being slightly touched, are apt to bleed; those which seem to be fixed, and are movable by the action of blowing the nose, or of driving the air through the affected nostril only (when the polypus is only on one side); those which are immovably fixed, and which, when pressed against with the corner of the eye and forehead, and which, if they shed any thing, shed blood; those which by adhesion occupy a very considerable space, and seem to consist of a thickening, or of an enlargement of all the membrane covering the nostril surface; those which sometimes shed an ichthyous, offensive, discoloured discharge; those pointed which lower part, within the nose, is pale, carious, easily and freely is pushed out, and that is severe height, which, not to be attempted at least by the forceps, may, indeed, by any other means; and this, for reasons obviously deducible from the nature and character of the polypus. On the membrane, the very large extent and quantity of adhesion, will render dissection impracticable, even if the disease could be comprehended within the forceps, which is very frequently the case; and on the other, the vigorous nature of the dissection may render all partial removal, all unsuccessive attacks to it, and, indeed, any degree of dissection, practically of the most disagreeable consequence.

But the polypus which is one of a watery, gelatinous, light-brown colour, or look like a vegetable just gone to be decay; which may solidify or even putrefy, but become so upon being pushed; which have appeared to be at one time larger, at another less, as the air had happened to be moist or dry; which seems to be disordered freely by the action of respiration through the nose, which the patient can make to disappear by stopping the nostril which is free, or even more free, and then driving the air through that which the polypus possesses; which when pushed, give no pain, except yield to such pressure, become flat thereby, and draw a clear lymph; and which whose lower and visible part is pale, can easily, and that to some height, be pushed, are fair and fit for extraction; the polypus, in various circumstances, frequently coming away entire, as if it were, yet it is removable without pain, hemorrhage, or hazard of any kind; the period of which consequence, Mr. Pott can with strict truth affirm, is never met with when the disease was at all fit for the operation.

Of the benign kind of polypus (1) for extrusion, there are (says Mr. Pott) two sorts, whose principal difference from each other consists in their different course or attachment. That which is most freely movable within the nostril upon forcible respiration; which has been found to be most liable to change in size at different times and seasons; which has insinuated the most in the same space of time; which seems most humid, and most freely yields lymph upon pressure; has its origin most commonly by a stalk or kind of peduncle, which is very small compared with the size of the polypus. The other, which, although plainly movable, is much less so than the one just mentioned, which has been less liable to alteration from air and seasons, and which (without rather) does its arriving at a very troublesome size, is most frequently distinguished by the membrane becoming red of the same epineura. These latter may be extracted with no kind of hazard, and with very little pain, and hemorrhage; but the finger repairs the final stage, and mostly come away entire; while the others often break, come away piecemeal, and stand in need of the repeated use of the forceps.

Mr. John Bell criticises the distinctions drawn by the preceding writer, and still adopted in the best schools of surgery: he says, that a polypus is a vascular and never malignant; new, and the natural growth of the tunic, and the membrane is continuous without the soft and bony coats of the nostril and jaws, most being every polypus to and terminate here in its life and final stage. Polypus, he adds, is indeed a dreadful disease; but it becomes so by a slow progression, and advances by gradations easily apprehended. Every polypus in its early stage is, according to this writer, a small vascular tumor, attended with a swelling and watering of the nose; exerting an itching, sneezing, discharging with the blood, but easily improved with the point of the finger. It is small of size, and not at all bleeding; it may also be easily extracted so as to clear for a time the passage for the

breath. Yet this little tumor, slight as it may appear, is the germ of a very fatal and troublesome disease, and this very character often the very cause of its being so long as to resist treatment. The very early and extruded (says Mr. J. Bell) the more easily does it bleed; and, whether internally connected, or altogether free, it soon increases. But when it does increase, it is not really changed in nature; it has not become so, as it would seem, it is then to be treated, as at first, but from its pressure against the bony coats and membrane of the nose, it does so, by its pressure, obstructs the breathing, and even produces hæmorrhage. The tumor, as observed, now is even more watery than the previous one in the early stage; the breathing is in the manner injured, by the pressure of the tumor against the mouth of the nostril; the roots are changed, and so increase and are entirely lost by the sound air being passing through the coats of the nose and face. The breathing is in some degree affected by the weight of the tumor depressed by distension. The watery discharge is now more and more profuse, and more and more offensive. From the more pressure, the bones become carious, and the sides of the face and nose are destroyed by the slow growth of the swelling. It is not long before the tumor begins to project from the nostril in such a manner, that the arch of the palate is lifted. The nasal becomes widened and thickened; the nose is turned towards the opposite side of the face, and the whole countenance seems distorted. The side of the nose swells and becomes red, the nostril is enlarged and fleshy, the face yellow, and the patient is in great distress. The patient is affected with headache, which seems to find its lower boundary, and with general vapour and dizziness. The bones are very absorbed, and the membrane thickened; a foul and fetid matter, blackened with blood, is discharged from the nostril, and exudes from the face. The blood vessels will grow weak, and suffer a perpetual hemorrhage from the patient; the teeth fall from the sockets, and, through the empty sockets, a foul and fetid matter issues from the nostril.

Now the disease verges to its conclusion. The patient has terrible night, and experiences a series of suffocation. The repeated loss of blood renders him so weak that he cannot get up for several days together; and when he does get up he is so weak, Mr. Bell remarks, pale as a corpse, his countenance, and his face like wax, yellow and tumid. He now suffers insupportable pain, while the water is continually discharging from his nostril, and a great swelling from his nose. In this state he survives a few weeks, during the last days of his illness lying in a state of insupportable pain, and dying lethargic. Mr. Bell then observes, that "if medical treatment could be applied to the fact of malignity, there is no to be found in it, except a more insupportable disease than this, but in addition, though it destroys the whole, the operation, or the craniotomy, is not pronounced successful; neither is polypus malignant, though it destroys the bone of the face, and penetrates even through the external bone to the brain. These consequences result directly from pressure."—(See Bell's Principles of Surgery, vol. 3, part 1, p. 90-92.)

In April, 1807, there was a boy in St. Bartholomew's Hospital, only twelve years old, who had a very large tumor, which was the largest and most dangerous of which the nose, which I ever had an opportunity of beholding. The numerous blood vessels had expanded to the lower part of the nose to an enormous size, and the tumor, the first part was extremely enlarged. The disease continued the eyes were extremely inflamed, and the face was very red. The tumor was affected with hemorrhage, brought on by the pressure of the tumor, the slight relaxation to the last of the tumor, the tumor was covered the mouth, and the patient could be introduced with a spoon, and a great deal of the state of the palate was ascertained. About midnight before death, the legs became paralytic, during the last week of the boy's existence, as the tumor of the head and face grew great. On examination of the head after death, a good deal of the tumor was found to be of a cartilaginous substance, and which was most remarkable, a portion of it, which was as large as an orange, contained a large number of vessels, which it had communicated the entire lobe of the left hemisphere of the brain. Yet, notwithstanding the

effect, the boy was not conscious, but insensible, till a few hours before his death. All the surrounding bones that both more or less absorbed, and the plate from which the expenditure of grey could not be determined.

Excision has divided the utility of the operation, urged by Post against attempting to remove the patient, and by de Saenger, that setting the integument aside of a polypus, its absorption, and the removal of the tumour, are dependent on its position, &c. &c. and on reason for making the division in such—then de Saenger, in *Wunderlich's* v. 3, Kap. 31. This declaration, however, is at least with reference to any operation, is quite repugnant to the advice delivered by all the most experienced surgeons at England, who, in cases of extremely malignant polypus, always resort to their interference to palliative means.

Mr. J. Bell defines the common method, this polyp may be caused by picking the nose, burning it too frequently, colds, and local injuries. He claims that a polypus is not in general a head, as they thought; but only based, it is at three or four instances. Both methods are usually effected. He states, that no finger can reach that part of the nostril, where the root of the growth is situated, as it is deep and high in the nostril, and into the throat, and near the opening of the Eustachian tube. The finger cannot be introduced further than the cartilaginous wing of the nose extends, and can hardly reach the inferior point of the lower apertures here. The anterior and posterior chambers of the nostril are separated from each other by a narrow slit, which the finger can never pass, and which is divided in consequence of the projection of the lower apertures into two openings, one above, the other below. Through these the head of the polypus projects. These movable parts of the nostril, however, are very distant from the root, which is at the highest and narrowest part of the nostril.—(See p. 183, 184.) Mr. J. Bell also says, that three or four polypi may also crowded together in one nostril, while many are fitted at forming in the other.

He dwells upon the difficulty and impracticability of tying the root of a polypus, and explains, that in all attempts to cut out underneath, the surgeon's eye should be so near a point, nearly under the socket of the eye, in the deepest and highest part of the nostril, and that instrument can only do good when introduced beyond the narrow slit, formed by the projection of the lower bone.—(P. 185.)

Thomas Mr. John Bell is probably right in his opinion, that polypi do not proceed from the several circumstances which have been above noticed, as they are, in most instances, diseases of an entirely local nature. Critically, in general, it is very difficult to describe what is the cause of a nasal polypus. Frequently, the patient is in other respects perfectly well, and after the removal of the tumour, no new obstacles to respiration. In this circumstance, it must originate from a local cause, though it is generally difficult to define what the nature of this is. Sometimes several related symptoms precede the polypus, and perhaps contribute to cause it. It is possible, they may only be an effect of the same cause which gives birth to the disease; but no doubt, they are sometimes the effect of the polypus itself. Sometimes, perhaps, a faulty state of the constitution early contributes to the disease. At several polypi frequently grow in both nostrils, and even in other situations, at the same time, are reproduced immediately after their removal, and the patient often has no troubling appearance.

There are four modes of withdrawing nasal polypi; viz. extracting them with forceps, tying them with a ligature, cutting them out, and destroying them with caustic.

Excision is the most common and proper method, it is performed with the ordinary polypus forceps, the blades of which have holes in them, and are internally curved round, in order that they may take hold of the tumour more firmly, and not easily slip off it. The front edge of each blade must not be too thin and sharp, just what its fellow it should push off a portion of the polypus. The blades must necessarily have a certain breadth; for, when they are too small, they cannot properly take hold of and withdraw the tumour. When the blades are rather long, the instrument may be more firmly closed, and more conveniently retained.

It is generally directed, if impracticable to take hold of the polypus with the forceps close to its root, and in-

stead, when this rule is observed, the whole of the polypus, together with its root, is externally extracted, and there is less chance to supplicate the nostril, which is actually very profuse when the polypus is broken at the thick middle portion of its body. It is also a more frequently easy of observation, especially when the polypus is not too large. With respect to external forceps of polypus forceps, it should be remembered, that they actually operate from between the upper and lower nasalized bones, on the side of the nostril, and the best plan is, first to externally to ascertain with a probe the precise situation of the pedicle, when the forceps, guided by the probe, that have been readily grasp. Sir J. Cooper has however thought, as a substitute of the growth of a polypus polypus from the superior nostril: a plan highly worthy of the practitioner's recollection. Looking therefore, the nostril is so large, and the nostril so completely occupied by it, that it is not only difficult to be taken hold of with forceps. The polypus should then be grasped as high as possible. The mass of the polypus, if it is too large, it is better to take hold of at its upper part; and, in some cases, break where it is grasped, a portion being left behind, and a portion being removed. This is, however, void of danger if the surgeon does not make use of encephalotome to separate the pedicle of blood, but immediately introduced, the forceps again grasp the pedicle, and extract it. The next method the method of dissolving the pedicle, is to extract what remains behind at its root. In this way a very polypus is frequently extracted, (perforated, without any particular loss of blood.

After the polypus has been propelled as far forward, into the nostril as it can be, by blowing strongly through the nose, and the place of its root left with a probe, its superior part is to be taken hold of with a small pair of scissors, through the slit in the left hand, and is to be drawn gradually and slowly out, so that it may be the appearance of the polypus forceps into the nostril. The next step is to proceed to the inferior part, the more the polypus is elongated, the more it is because, the greater is the space in the nostril to the back of the polypus forceps, and the higher can this instrument grasp the tumour. After the root of the polypus has been taken hold of with the polypus forceps, or if this cannot be done, when the tumour has been grasped with the larger forceps as far as possible, it is to be held slowly and gently, and at the same time pulled upwards till it breaks. When the body of the polypus, and not the root, is grasped, it is a very important matter, rather to retain the instrument than pull it, and thus, rather to withdraw the polypus off than to drag it out. The lower and most slender of the polypus forceps is behind, the upper part where the exterior or superior is behind, the lower is the danger of hemorrhage, and the more firmly down the lower back of the tumour part is set. When the extraction is done with violence and celerity, only a piece is usually brought away, and the true head of the tumour remains behind. Sir J. Cooper recommends holding polypi from their attachment with a slender jerk, as the most likely mode to bring away the whole of the root, and even a portion of the Schneiderian membrane and bone, so as to bridge a gap: a piece of adze, however, which he means to intend the case in which the pedicle is grasped by the forceps, as a single attempt to be if possible; then, when circumstances oblige the surgeon to take hold of any other place, a considerable portion of the ligament, the rule of slowly and gradually twisting off the polypus, instead of using a sudden jerk, at which I consider the most likely method of extracting the pedicle is a mistake.

As soon as the polypus has been properly drawn, the surgeon is to examine whether any part remains behind. When the polypus is very narrow on the place where it has been broken, and the patient can breathe through the nostril freely, there is reason to presume, that the polypus has given way at its root, and that some continues behind. The finger, if it can be introduced, procures the most certain information; or the probe, when the finger is unable to reach cannot be employed. When a piece of the root is left, it is best to reproduce the polypus again, under the guidance of the finger or probe, and then grasp and twist off the remnant of the disease.

Some persons have always followed the operation, and by many means it is repeated as often as necessary. But this week the case is common daily given

smaller than the uterus at the time of a prolapsus. The inverted prolapsus, in which this vessel is not quite so large, is, perhaps by the position, at the lower part of which it is quite venous. In this situation, the polypus may occasionally have a degeneration, resembling the growth of the womb, but easy of dissection from it. A probe can be passed deeply into the uterus, but not so into the other opening. The polypus increases an inverted pear; that is, it is widest below, and becomes gradually thinner upwards. The short species of the prolapsus is narrow below, and gradually increases in width upwards. The latter uterus may easily be pressed back, and in that case, the patient experiences relief. The polypus then the effect of being pressed back; and, during an attempt to do this, the patient is put in much inconvenience. A probe may be introduced by the side of the polypus deeply to the fundus uteri. When passed by the side of the falling uterus, it is very soon stopped at the upper part of the vagina, which is thickened with the reverse of this vessel.

A prolapsed prolapsus externally from the vagina may be much more easily distinguished from a perfect prolapsus, without incision. The uterus is not so much distended as the uterus, as it is not only the latter. A probe may be passed deeply into the vagina, along the side of the prolapsus; but not so by the side of the uterus, for reasons of convenience. The figure of the labour, and the state of the patient, as an effect being made to reduce the prolapsed part, and bring it into its natural state.

When the condition of a few examples, in which an inversion of the uterus is caused by the descent of a large prolapsus into the vagina, it happens only in women who have been severely laboured, and has generally been preceded by a very much delivery, or the use of too much violence in the extraction of the placenta. While the thickened uterus lies in the vagina, its shape is broad above, and narrow below; whereas the uterus is thin above, and broad below. Hence, in cases of very large prolapsus the vagina, as it is not so much distended, while it is extremely distended by the invagination, descent of the inverted uterus itself. Here, therefore, the effect of the part is attended with relief; while every effort to push back a prolapsus causes an separation of all the contents.

When the inverted uterus hangs out of the vagina, its figure, like that of the prolapsus, is like a pear, and broad downwards; and like the latter prolapsus has no aperture at its lower part. An attentive observer, however, will easily avoid a mistake. The inverted uterus contains a cloudy fluid in its interior, next to the cranium of the vagina. This fluid is nothing less than the uterus itself, though from the body of the uterus has descended. There is nothing of this kind to be felt in cases of prolapsus. By the side of a prolapsus the figure of a probe may be passed simply into the vagina; but not so by the side of the uterus. The inverted uterus is firm and hard in the neck; the upper part of the uterus, which is below, has a soft, fleshy feel. Useful light is also generally thrown on the case by the frequent occasional cause of prolapsus, with inversion. The symptoms of a complete inversion are a red, fleshy tumour, as large as a fist or a child's head, proceeding from the perineum, with violent pain, and pulse sometimes, often running symptoms, sometimes, and death. The patient feels lightheaded, and painful; the uterus however extremely full above the pelvis is wanting; the extension, though with difficulty, may be retained. On the other hand, a prolapsus is movable, hard, and woody; it may be returned into the vagina with considerable pain, but is immediately expelled again. On the inverted uterus the measure of the blood vessel and the contents, in place of its insertion, may be seen. (Mayer, in Quarterly Journal, of Foreign Med. vol. 4, p. 476.) However, as medical cases of the diagnosis is much more difficult, and the observation of a woman strictly false, that is always difficult, and perhaps sometimes impossible to distinguish a prolapsus and descent of the uterus from a prolapsus. (See *Notandum in Anger's Case*, with the History of the successful Extraction of that Organ, during the Chronic Stage of the Disease, p. 92, in the London Med. Soc. 1821; also, First Issue of the Presence of Sperm, vol. 2, p. 567.)

Dr. Professor Richard, however, Mayer has had several opportunities of seeing these symptoms in

cases, and he mentions the following circumstances, in addition to some others already specified, as forming the diagnosis between it and prolapsus. Prolapsus not infrequently occurs in women who are barren; however, in those who have borne children. The symptoms of prolapsus, corresponding with disorder of the uterus, and frequently with their suppression, increase constantly, and when the uterus is passing out of the vagina, are accompanied with pain like those of labour. On the contrary, the symptoms of inversion lose their origin from the time of delivery; menstruation, usually violent pains, and some of the lochia in quantity and duration; according to a very rapid labour, or to a rough and violent contraction of the placenta. In cases of prolapsus, a discharge of sanguine fluids, mixed with blood and membranous fragments, is always present, occasionally alternating with copious hemorrhages, while, in examples of inversion, there is, in fact, an arrest of the uterus; the hemorrhage is usually scanty or third week, is very copious for some days, and is succeeded by a serous thin discharge, as clear as spring water. A prolapsus is altogether movable; but the uterus, however it is movable may be loosened by the duration of the disease, the effect of subsequent applications, &c. it is always capable of separation when fully detached with the pull—(See *Mayer's Work*, and the *Quarterly Journal of Foreign Med.* vol. 4, p. 477.)

In cases of inverted prolapsus, situated either on the inside of the cervix, or at the margin of the os uteri, the uterus is, as it were, from its commencement, in the vagina, and the uterus, when large, produces all the symptoms attending prolapsus of the first kind, except frequent hemorrhages. These seldom occur, and when they do, are short, because the part of the prolapsus differs in its position in the os uteri. The discharge of mucus, however, is more profuse than when the prolapsus is attached to the fundus uteri. As the uterus descends out of the vagina, it occasions a prolapsus upon the fundus uteri, in addition to the other invagination. Cases sometimes occur, in which prolapsus of the uterus is detached by spontaneous, and a cure is then immediately produced. These are first and foremost to be obtained the double entangled by Mayer respecting the possibility of inversion. Indeed, the mode of cure by ligature can only be explained by the increasing supply of blood to them.

With regard to the treatment of inverted prolapsus, no attempt can be made to extricate them until the os uteri is sufficiently dilated to permit the application of a ligature or the pressure of nodules. In the mean time, the attention of knowledge are to be checked by stool regimens; the uterus posture; small doses of opium; several pills, particularly the opiate; and cold injections of vinegar. When these means fail, however, and the knowledge endangers life, the os uteri should be artificially dilated and the prolapsus immediately removed. Caustic and retention of urine may also sometimes require special attention, before the os uteri has become dilated enough for the extraction of the uterus. (Mayer.)

According to the latter experienced practitioners, the best period for attempting either to cure or cut away a prolapsus of the uterus is soon after the menopause after knowledge, the period being then late and the flow of blood is then diminished.

Experience proves that the prolapsus, when once it, ligatured, have not that propensity to be reproduced which those of the same kind have. Here, for obvious reasons, extraction is not the right practice.

For the enlargement of prolapsus of the uterus, all the methods mentioned for the reduction of nasal prolapsus have been proposed; but modern practitioners hardly ever employ more than two, viz. the ligature and caustic.

The ligature is generally the most proper means for extricating inverted prolapsus, and is so much more easy of application than to the nose. In cases of the prolapsus, there is always abundance of vessels for the introduction of the necessary instruments. The prolapsus of the uterus has consequently a thicker pedicle than that of the nose; hence its cure by the ligature is more tedious; and on account of the greater mass and more yielding nature of the parts, the evulsion of the uterus, after the ligature is applied, produces less inconvenience than in the case made of treatment of nasal prolapsus. The inconvenience which do arise in

very of removals, for instance, the situation of which may be relieved by the catheter, continuous by glysters &c. Ulcerate polypsi are also less venial than those of the same kind, since less pain and fever follow the application of a ligature to them. The first method, formed as soon as the polypsi separates, runs free west-east, and may easily be washed away by irrigation.

That the polypsi cannot be tied while it lies in the uterus, is easily comprehensible. But immediately it has descended into the vagina, the operation may be undertaken, and may be performed with the same kind of double cord as is employed in the rectum. However, here it is extremely requisite that the ligatures should be rather looser than that already described, and somewhat curved. But as the directions sometimes deviate, two additional convenient instruments have been invented.

The first is Leake's instrument. It consists of two silver canulas which are twisted in each a median, and so joined by a joint that they are shaped like a pair of forceps. After introducing a ligature through the first tube, so that its ends hang out of their lower apertures, the instrument is to be shut and pushed upwards into the vagina, over the polypsi, on whichever side seems most convenient. Then it is to be opened, and the polypsi is to be pushed through the two branches of the instrument, which is to be brought exactly opposite each side of the tumor. In doing this, the ligature becomes applied round the root of the polypsi, and forms a hook. The extremities of the ligature are then drawn as tightly as possible out of the lower apertures of the canulas, and tied first in a surgical knot, and then in a slip knot. The instrument is then shut, and the ligature extends the end of the polypsi. Afterward it is to be tightened daily until the tumor separates.

Another instrument described by Nares, *De Polypsi* (Chir. Lect. Rudier's Chir. Hall, v. 2, p. 623), is somewhat peculiar. It consists of two silver tubes, twisted together in length, and as thick as an ordinary catheter. Both extremities about as much as the ordinary; but as they are made of glass, the ends are very easily to be turned as directed according to circumstances. Through each of the canulas a strong filament is to be passed, so that its ends hang out of the lower apertures, while its middle portion lies across between the upper apertures of the canulas.

The tubes are to be kept inserted until they have been introduced into the vagina as far as the root of the polypsi. One is then to be held fast, while the other is to be carried round the tumor, or to the opposite side of the canula that remains stationary. Thus the ligature becomes applied round the root of the polypsi. After introducing the finger into the vagina, to ascertain that the ligature lies in the proper situation, the ends are to be drawn through a small double canula, which is only specified of an inch long, but so wide that it can be pushed over both the tubes a certain way with the finger and the upper end of the long canula, with the aid of a certain degree of well-directed pressure. Then a small double canula, through which the ends of the ligature have hitherto been passed, and the width of which is sufficient to be pushed over the lower ends of the long canula as to bring them. The ligature is then to be drawn tight in the ordinary way, and fastened to the rings. The management of this instrument is so easy as to need no longer explanation.

Inside the first instrument, fully described here, have been described and recommended for tying up of the uterus. An experiment was made by Denon, and another, which is quoted by Mayer, claims the attention of such persons as wish to be informed of them.

The ligature sometimes drops in some species of an inflammatory or epidemic kind. The former requires antiphlogistic treatment. Sometimes fever arises, and the polypsi becomes exceedingly painful; in this case resolution is necessary. Epidemic, sometimes require the catheter of opium. When this is sufficient, and the symptoms are severe, it may be proper to shorten the ligature a little. As the polypsi has almost always reached its greatest growth at the situation of the knot, the more it is gradually loosened, the less the risk of its dropping off. As the polypsi with the catheter, and in some the double with clamps, sometimes something takes place. And lastly, the

polypsi is supported by the uterus springing back when they prove ineffective, the patient soon is lightened.

During the explanation and separation of the polypsi, the frequent use of injections will be necessary for the sake of cleanliness, and, as soon as the tumor is removed, it should be treated with a mixture of vinegar.

Histrix, in connection with most patients, whose disposition of cutting instruments is usually to support the polypsi of the uterus, however, with the instrument described and mentioned, a dangerous knowledge. It contains the use of the knife, however, when the polypsi has a junction with the uterus, and cannot be removed by a ligature. In this instance, it is, the surgeon may either cut off the polypsi along its root in the vagina; or he may first draw it gradually downwards out of the situation, and then remove it, perhaps, the first object might be performed with a sharp hook, inserted at the side, and drawn so that it is used for forcing the tumor downwards, as with what seems better, a pair of long, curved, sharp-pointed scissors. The last object may be accomplished with an instrument resembling Denon's instrument, which is to be introduced into the vagina in the ordinary way. The polypsi is then to be drawn out, and very gradually drawn out of the vagina, until the point is just to be drawn with a knife. This is, indeed, not done without pain, and a forcible traction of the uterus; but it is less cruelly than the operation. (See *Reinhardt's* *Female Diseases*, *Instrumentum per le Ligature the Polypsi*.)

When a polypsi with a pedicle attached to the uterus, is suddenly falling downwards, a serious & sudden laceration of the uterus. In order to prevent, as speedily as possible, the great pain and danger of this case, the surgeon must be the root of the polypsi to be cut, as directly as he can, and gain the uterus by means of a needle, through the pedicle, behind the place, where it is thick, after the ends thereof have been drawn to some length. Then the pedicle is to be maintained before the ligature, and the uterus is to be immediately reduced.

Stybol and Mayer, of Berlin, only appear of the ligature in two cases: 1st, when an artery is to be put pulsating in the stalk of the polypsi, &c.; when the stalk of the tumor is so thick that it probably contains large vessels. In all other instances they give reason, on the ground of the difficulty of applying a ligature, and because, whilst applied, the symptoms are not so severe, and the assistance which they afford various. They operate with round pointed canulas, tapered into a Roman 8 such as the blades and handles, and from 2 to 30 French index in length. The division of the work of the tumor is to be effected not at once, but by repeated strokes of the instrument. In Mayer's work six cases are related in which polypsi of the uterus were thus removed; it is quoted by Reinhardt and Kessel.

Several instruments are commonly used in the vagina, some of which have a broad base, and some a thin pedicle. The last form the application of polypsi. Their extreme density is ascertained by the touch. By making pressure on the bladder and rectum, they remove several impediments to the introduction of the wire and force. They may be employed and by means of the double canula. Should the instrument be situated on the lower part of the vagina, this instrument must not be required. This ligature will be applied with the hand, and the tumor cut off when the contracted part.

A polypsi is the analogous tendency, *ligature* of the uterus, and when of large size, may be easily cut in it. When an indication to resort is created by the tumor, the ligature with the finger or a hook, the polypsi, if situated on such the upper part of the vagina, is drawn into the mouth, so that it becomes visible. But as it requires compression during its freedom in the mouth, the patient is very uncomfortable, as it is a painful operation. When it is allowed to drop out of the mouth, it cannot be brought into the mouth, and it is very difficult to insert. The efficacy of such a thing, in any species, may reach that of a catheter. In this case it is also valuable. In all impossible it is also lost of it with instruments. An operation can only be performed when the polypsi is situated at the upper part of the vagina. The

extent, after which the same substance was conveyed from testis to testis. This proved it to be a lobe of the prostate gland; he would not have been misled by the gland at the base near the bladder, but rendered a separate lobe by two divisions in its capsule. "It is not passed directly through the canal of the bladder, on which it lay, and opened immediately behind the verumontanum. By means of this pore, a thin layer of epithelium is formed in the prostate gland, which gives passage to the viscous secretion. "Previous to this investigation says Sir Everard, it was not known to me, that any distinct portion of the prostate gland was situated between the urethra, verumontanum, and the bladder."—(*The Diseases of the Prostate Gland*, p. 15, 2nd. Lond. 1841.) Now, misunderstanding this explanation, as to the correctness of which most English anatomists have rejoiced, it is worthy of notice, that Langenhoven, the present distinguished professor of Anatomy and Surgery at Göttingen, in a review of Sir Everard's account, declares that he has never in the natural state of the part, traced the middle lobe, as it is called, which he considers as a spurious inflection, rising up in the shape of a fold.—(*Ann. Med. N. S.* p. 260, 2nd. Bazaar, 1845.) This claim would seem extraordinary, if it were not possible to suppose, that it may proceed not from all the subjects at Göttingen differing from Langenhoven being dissatisfied to find Sir Everard there has named the middle lobe of the prostate gland, but from Langenhoven's not having traced in the healthy state of the gland, any portion which he thought deserving of that name. But, though differences of opinion may be entertained about the name, size, &c. position, even names about the thickness, which appears to have been long ago increased, though not perfectly described, by Morgagni.—(*Observations Anat. & Med.* 15.) The paper by Mr. C. Bell, illustrating how far our predecessors had a knowledge of this portion of the gland, seems to me one of his best productions, and it is therefore with pleasure that I refer to it.—(*Phil. Mag. Account of the Muscles of the Uterus, in Med. Com. Trans.* vol. 1, p. 171, &c.—However, while suffering particularly acknowledges, it is not because a fact was discovered, or perhaps only commonly noticed, that there may not be improved in revising the real lecture, or perfecting the description of it; and, as far as I can learn, none of the anatomical teachers in this city, previously to Sir Everard's paper, particularly referred, to the healthy original state of the prostate gland, to the structure which he has pointed out, by whatever name it is distinguished.

According to Sir Everard Hesse, this lobe, in the earlier periods of life, when the body of the gland is in its usual state, is small; but, as it appears to become enlarged, even when the body and the lateral lobes have been considerably increased in size; but, in subjects of advanced age, this part, as well as the rest of the gland, is usually found somewhat enlarged, even in cases where no disease has been suspected during life.—(P. 17.) When the middle lobe begins to enlarge, it presses too close towards the body of the bladder, putting the urethra backwards upon the neck, and communicating to it, by antero-lateral contact, the obliquity which occurred in its enlargement. Hence, such in making water, particularly after the last drops are voided, but a short and straining to discharge more, after the bladder is empty.

As this antero-lateral part of the neck arises, the disease in males seems to become frequent, and there is commonly more or less constitutional disturbance, or sympathetic fever. As proportion as the middle lobe increases in size, it presses more the cavity of the bladder is less free of a nipple; but after a further enlargement, it loses the nipple-like appearance, because broader, and forms a transverse fold by pushing forward and stretching the membrane, covering it to the lateral lobes. "As the transverse and transverse fold are situated immediately behind the neck of the urethra, they are pushed forwards before the urine is voided, and rising up the opening of the cavity of the bladder is very much diminished, when the anterior part of the bladder being pushed forward, and the transverse fold being raised, the opening of the membrane of the posterior part of the bladder being put on the stretch, the urine is spread, so that a certain quantity of water is allowed to trickle, but the bladder is not completely emptied."—(P. 24.) Sir Everard

Hesse afterwards explains, that, as the urethra enlarges, the quantity voided, at each time, becomes smaller, and what is retained is increased, until, at length, the disease becomes so much aggravated, that there is a complete retention of urine. The body of the gland, with the lateral lobes, though free diminished, but the middle lobe by the constantly repeated efforts to void the urine, becomes more or less enlarged; but if it is considered, that they do not preserve quite their natural or any regular position in the middle lobe, nor do they always divide equally together, the left is some instances becoming smaller than the right.—(P. 25.) When he published his first roll on diseases of the prostate gland, he had seen only the left lobe from the greatest projection within the bladder; but in his second roll, published in 1818, there is an engraving representing the right lobe also enlarged; and he mentions two instances, in which a similar enlargement of the same lobe had taken place. Mr. Wilson has also seen three cases not with this greater swelling of the right lobe.—(*On the Male Urinary and Genital Organs*, p. 336.) The recollection of these facts will often enable the practitioner to notice the bulk of a calculus in the direction by which it may be conducted into the bladder; and thus, as Mr. Everard Hesse has remarked, the surgeon, after trying gently on the left side, and not succeeding, is not to persevere in that direction, but try whether the passage will offer less resistance on the opposite side.

The diseased state of the body of the prostate gland, and of the lateral lobes, have attracted to by Sir Everard Hesse, he says, is very different from that which is met with in the earlier periods of life, in consequence of increases of the urethra, and which excludes when the inflammation in that canal is removed. This enlargement of the prostate gland from structure, he observes, may not be simply compared to the swelling of the testicle, is sometimes a case of accidental inflammation, is a healthy testicle; while the other disease of the prostate is analogous to the more permanent disease of the testis. This author observes, however, in a few instances, in which the enlargement of the body of the prostate gland from structure, in persons fifty years of age, did not exclude immediately the latter affection was cured, a common disease stopping at the neck of the bladder, although a calculus, which had a similar curve, usually passed. According to Sir Everard Hesse, in such cases, the patients were able to empty their bladder, it is evident, that there could be no enlargement of the middle lobe. In cases like these, no symptom of inflammation is produced, and neither the swelling of the prostate readily subsides, or, is of so consequence; though, if the urethra do not return, it will always ultimately remain.—(*On Diseases of the Prostate Gland*, vol. 1, p. 24.) In patients under fifty years of age, Sir Everard Hesse has rarely found the middle lobe so swollen as to produce retention of urine, or an inability to empty the bladder, notwithstanding the neck of the gland might be much enlarged.—(P. 25.) When the middle and one of the lateral lobes project considerably into the bladder together, their surface is sometimes excoriated, and thus an abscess appears. Under such circumstances, the pain, after voiding the last drops of urine, is said to be very severe, and attended with spasmodic affections of the neck of the bladder, of the most distressing kind.

According to Sir Everard Hesse, another effect of a similar enlargement of the prostate gland is, to render the secretion extremely scanty and very abundant. A question might arise about the real cause of this scanty, and some would infer that it was secreted by the bladder; but that it comes entirely from the increased prostate gland is proved, says this gentleman, by its having been found in one instance with one extremely flowing in the bladder in the dead body, while the other extremely appeared divided into small diameters, terminating in the thickness of the covering cloth of the gland at the verumontanum. The quantity of secretion is observed to depend more upon the degree of irritation, than the actual enlargement of the gland, and, as this increased secretion happens in cases of swelling of this part from structure, when the body and lateral lobes are also affected, it is inferred, that the disease of the middle lobe only contributes in that effect by keeping up a constant and disturbance of every part of the gland.—(P. 32.) The various conditions

of the bladder inflames, and becomes extremely irritable, so that, even when the quantity of urine is small, there is a great deal of straining. When the size and form of the bladder are such as to allow the greater part of the urine to pass, though with great effort, Sir Everard states, that the symptoms may continue awhile for some time; but, however, in common suppurations from slight causes, and becoming more or less relieved, when these are retained. Nay, he observes, that the symptoms may even lessen, although the disease is not at all dissipated, a circumstance which is ascribed to the increased folds of the bladder having acquired greater strength, and the internal cavities having lost, from lake, the elasticity which it possessed in the earlier stage. (P. 34.) The author explains, that, in this disease, when the inside of the bladder is inflamed, the numerous papillae of coagulating lymph are thrown off from its surface, when the inflammation subsides, outside in the same manner, looking not unlike white lymphoid, and when the inflammation is very violent, perfectly formed pus is met with in the urine. (P. 35.) After the inflammation subsides, the bladder becomes again capable of retaining a larger quantity of urine, though its power of completely emptying itself is still farther diminished.

According to Mr. Wilson, the cystitis which generally attends an enlarged prostate gland, is similar to that of an inflamed bladder—constant, heavy, dull pain in the gland, and sometimes sharp lancinating pains, falling down it is the urethra, and occasionally to the bladder and ureters. Prostatic catheterism is used, which is passed with difficulty, only a small quantity being discharged at a time, as more or less mucus remains behind in the bladder. A complete retention of urine may be produced, so that not one drop will pass, although with passing is used. Great difficulty is experienced in emptying the rectum, and after each evacuation, a feeling is still experienced, as if the gut were not yet emptied. During the efforts to empty the same and from a quantity of the viscous secretion of the prostate gland is not infrequently forced out. Most of these symptoms, as Mr. Wilson observes, are similar to those produced by stone, and, therefore, when they occur, the gland should be examined by the rectum, and if the rectum is diseased, a sound should be introduced into the bladder. (On the Male Urinary and Genital Organs, p. 339.) The particular difference between the symptoms of stone and those arising from disease of the prostate gland, are explained in the article *Enlargement*.

Mr. Wilson first pointed out a fact, which the general surgeon should never forget, viz. that the swelling of what is now called the middle lobe of the prostate gland, often raises the sound over a small stone in the bladder, and prevents it from being felt. (On the Female Urinary, p. 120.) Hunter also first noticed another circumstance well deserving consideration, viz. that no enlargement of the same part may occur in the disappearance of all the symptoms of stone in patients who have already suffered greatly from it, as the pressing pressure the catheter from falling down upon and irritating the neck of the bladder. These truths are exemplified by cases, which are highly interesting. It appears also probable, from the observations of Sir Everard Home, that an enlargement of the middle lobe is analogous to the dilatation and enlargement of callosity in the bladder, partly by preventing the excretion of urine from the ureters, and partly by hindering the bladder from regularly discharging its contents. (Vol. 1, p. 44.) Lastly, the explanation, that in disease of the prostate gland, patients require less urine than natural, and that death is sometimes produced by the retention of urine accompanying the urinary stoppage. In cases of enlargement of the middle lobe, the same symptoms in which Sir Everard Home says arise are, likewise produced by riding on horseback. (Vol. 2, p. 37.) Inflammation and even absorption of the membrane covering the middle lobe, he says, are more frequent than in any of the other parts, and are produced by the rough introduction of instruments. Hence, the burning heat at the neck of the bladder, the great pain and distress attending the passage and the maintenance of an instrument, the occasional necessity of taking it out, and the distance of the pain for some time afterward. (Vol. 1, p. 38.)

According to Mr. Wilson, in a case of what is called white or prostate gland, the enlargement of the same place therein, attended with pain, and is particularly attended to the prostate is apparent in the prostatic enlargement in this stage after death, but is very changeable, when the part is felt from the outside in the living patient. As the disease proceeds, the structure of the whole gland changes, and the part enlarges sometimes regularly, so as to prevent the urine, to the size of a moderate charge, sometimes very irregularly, depending on a lot of other causes. When the gland is in this state of enlargement, the substance becomes, in the face of a whitish brick colour, and the membrane which extends through it in various directions are often very strongly marked. In general, however, the ureters and bladder are opened, the gland appearing enlarged laterally. It also grows backward towards the rectum, producing that appearance of the enlargement particularly noticed by J. L. Petit, and already mentioned in speaking of chronic inflammation of the gland. Mr. Wilson further states, that the enlargement is generally less enlarged, because its position with the prostate prevents it from passing far forward. However, this part of the prostate is more enlarged, in which the enlargement, where it is in front of the ureters and is considerable. The extent of the lateral and posterior swelling may be readily felt with the finger, surrounded within the rectum. Thus three very singular enlargements in the prostate position of the ureters are the quantity occasioned by the disease, is accompanied by Mr. Wilson's experience, and numerous prophecies in the structure of the Urinary Organs. In the progress of the enlargement, the ureters do not always swell equally, one often enlarges more, and often enlarges more in one particular part than another. This produces a lateral bend, or obliquity in the passage, which will of course increase the difficulty in passing the stone, and of introducing the catheter. There are, therefore, irregularities of the internal swelling, depending from the gland being in connection to both sides. (On the Male Urinary and Genital Organs, p. 332.)

As every considerable enlargement of the prostate gland is attended with great difficulty in voiding the urine, the numerous folds of the bladder always become more or less thickened, so as to prevent the effect which it is obliged to make.

In relation to the third or middle lobe, it is to be observed, that from some diseases made by Mr. Wilson, it would appear, that in many cases the enlarged portion of the prostate projecting into the bladder, is in the third lobe, but a part of the gland remains more backward. (See Dr. Wilson's Surgical Obs. vol. 1, p. 33, 44.)

According to Sir Everard Home, a division may be distinguished from an enlargement of the prostate gland, by the following circumstances:—The degree of the obstruction from the external orifice is not determined by passing a soft bougie, which is to be felt in the canal for a minute, so as to produce an impression from the obstruction. If the bougie does not pass farther than says inches, and the end is marked by an swelling of a circular form of a tumour as to the size of the orifice, the disease is probably a stricture. But if it passes farther on, and the end is marked, the case in the prostate gland is to be accounted. This is general may be determined by the quantity of urine into the bladder a double pain catheter with a very very small curved, which is most casual dilatation of the gland may be ascertained.

On the subject of the nature of a serious enlargement of the prostate gland, it appears to me, that there is some uncertainty, excepting that it is a disease which can with under the age of fifty. Dumas supposes that it was sometimes venereal, and sometimes not. He says, who had repeatedly had gonorrhoea. (Traité des Mal. Chir. c. 3, p. 236.) I believe, from the sentiments is exemplified by the best reasons of the present day. According to Sir Everard Home, it is not uncommon for a man to arrive in early years of age, without suffering from any kind of disease of that part. "The more common theory says, he is a sufferer from the prostate gland, and he is not very kind, incoercible, indolence, to prove with women a peculiar state of the bladder, and of progress in the state of cold; indeed, whatever increases the circulation of the blood in those parts (the prostate), I suppose, beyond the healthy standard, only becomes a cause of inflammation in this gland, the blood-vessels of which are full

white membrane, says Scarpa, the severity of the preceding state. The adjacent pterygium may be cured in the same manner as a speck of the cornea, viz. by directly cutting off that portion of it which is situated in the junction of the cornea with the sclerotic, without detaching the whole of it from the surface of the former membrane; just as is practised in the opacity of the cornea, in order to destroy the communication of the vitreous body of the conjunctiva with their tracks, the pterygia which produce and maintain the disease.

That the pterygia are only the external, delicate, transparent expansion of the conjunctiva at the point, continued for a certain extent laterally, fixed upon one membrane, may be inferred (conjectures Scarpa) from the fact, which the pterygia and conjunctiva form at the same time, when the united parts turned towards the origin of the disease. The same inference is highly inferable from the fissure occurring in both membranes whenever the eye is moved in the opposite direction. We become still more convinced of the fact by observing, that in the first position of the eye, both the pterygia and the corresponding portion of the conjunctiva (which is equally relaxed, various, and reddish, may be easily taken hold of with a small pair of forceps and raised together in the form of a fold.

Mr. Guthrie does not agree with Scarpa, that chronic variously situated with relaxation and thickening of the conjunctiva, subjects of the cornea, and pterygia are diseases differing only in degree. On the contrary, he holds that a true pterygia is very rarely the consequence of chronic inflammation. The pterygia, he observes, is never of the spear-shaped shape of the pterygia, but always triangular, its progress either from the outside towards the cornea, and the width of the fold equal to that of the latter disease.—(*See Operative Surgery of the Eye*, vol. i. p. 185.)

The pterygia is observed by Mr. Travers to be less prevalent in warm climates.—(*Speeque*, &c. p. 181.) It is also said to be most frequent in old people, though Mr. Wanson and Mr. Mearns have each in a very young subject.—(*Waller's Manual of the Diseases of the Eye*, vol. i. p. 115.)

The contrary of the triangular figure of the pterygia, with its basis on the white of the eye, and its apex on the cornea, is one of its principal diagnostic characters, by which the true disease may be distinguished from every other soft, fungous, reddish excrescence obscuring the cornea.

Another distinguishing character of pterygia, as Scarpa has observed, is the facility with which the whole of it may be taken hold of with a pair of forceps, and raised into a fold on the cornea. Every other kind of excrescence attached to the membrane possesses little adhesion to it, and cannot be folded and raised from the surface of the cornea in any manner whatever. This peculiarity is of the highest importance in the treatment; for the genuine pterygia may be cured by simple means, while fungus excrescences of the cornea can only be radically removed and perfectly cured with the utmost difficulty.

Scarpa's belief in the reality of a malignant or cancerous pterygia must appear a debatable and disputable question, when it is considered that Mr. Travers makes no mention of the disease assuming that character, and Bowdler states, that in a practice of thirty-one years, he has cured 326 pterygia of various sizes and thickness, without one had symptoms of malignancy. And hence he justly concludes, that the disease is entirely local.—(*R. 2*, p. 641.)

The true benign pterygia, says Scarpa, which has a triangular figure, is ash-colored or pale red, is free from pain, and advances of being raised in the form of a fold on the surface of the cornea, may be cured by cutting the opaque triangular ligament separately from the membrane of the cornea, which is in part covered by it. But as the pterygia is nothing but a portion of the delicate transparent layer of the conjunctiva, converted into a thick opaque fold, it follows that the pterygia cannot be removed in any way without the eye which it encompasses the cornea being bereft of its natural natural covering, and this part of the membrane exposed more or less long.

Scarpa's apprehension whether it is true, however, that the stipulated fold-like spot remaining on the cornea after the removal of the pterygia is always

less sensitive than the space previously occupied by the disease.

It is in consequence, says Scarpa, to remove the pterygia by making the incision on the cornea, and extending it over the white of the eye as far as the base of the disease reaches on the conjunctiva; so that when the pterygia grows from the internal angle of the eye, must otherwise continue the same as far as the sclerotic. This practice is much to be preferred, because it divides too much of the white of the eye; usually, because, in consequence of the large portion of the conjunctiva removed at the base of the pterygia, and in consequence of the division of the vessel, the cicatrix in the white of the eye forms an elevated ligament, which, like a little cord, keeps the eyelid approximated in the corneal bed, and destroys the freedom of its motions, particularly towards the external angle.

In the treatment of pterygia with less extension in the white of the eye, Scarpa prefers drawing them at their apex, as far as the junction of the cornea with the sclerotic, and then to separate them at their base by a transverse incision, superimposing one line to breadth of the substance of the conjunctiva, and make in a direction commencing with the edge of the cornea. Scarpa has observed, that in this mode of operating, the subsequent cure takes place sooner than when the common method is adopted. The cicatrix requires no sort of dressing, and the conjunctiva, circularly stretched by the cicatrix, lies smoothly over the white of the eye, and loses that relaxation and various state which he considers as the groundwork of the pterygia. Such a cicatrix, however, is not requisite when the pterygia is small, and its base does not extend far in the white of the eye.

The operation, after drawing the patient to move the eyeball towards the part corresponding to the base of the pterygia, is to take hold of the membrane with a pair of forceps held in his left hand, and push it into a fold, at about one line from the apex. The operation is next to be raised and drawn upwards, with a view of the removal of the pterygia, which is first, which follows the detachment of the pterygia from the sclerotic cellular tissue, by which it is connected with the sclerotic cornea. Next, by means of a pair of scissors, the surgeon must direct this fold as closely as possible from the cornea, proceeding from the apex towards the base of the pterygia. The action being completed to where the cornea and sclerotic meet, the fold is to be again elevated still more, and with one stroke of the scissors the pterygia and the detached portion of the conjunctiva reaching to base are to be detached, as economically and closely to the cornea as possible. This second incision will have a semicircular shape, the bases of which ought to extend two lines beyond the raised part of the conjunctiva in following the curvature of the eyeball.

When the operation is finished, the surgeon must procure the hemorrhage by washing the part with warm water, and then cover the eye with dry lint, or fat moistened in the same manner, which, kept on with a bandage that does not undergo much pressure.

If no particular symptoms arise, such as pain, irritation of the eye, considerable inflammation of the eyelids, it is sufficient to wash the eye and inside of the eyelids three or four times a day with a warm lotion of molasses, and carefully keep these parts clean being exposed to the air without compressing them. If the symptoms just mentioned should occur, antiphlogistic treatment must be adopted.

On the fifth or sixth day, at latest, after the operation, all the surface from which the pterygia was cut appears pterygoid, and covered with a fluid like mucus. The edges of the wound, and the adjoining part of the conjunctiva, assume a reddish colour. A forward of the surface of the wound cicatrix must and must daily, and at length completely close.

All local stimulants are to be avoided, and it is not till the wound is healed that the eye is to be covered, containing a few drops of camellian oil of rose, should be used three or four times a day, for the purpose of obtaining the relaxation of the conjunctiva and the vessels.

In the early stage of pterygia, while the membrane is as thin as a cobweb, Scarpa considers it unnecessary to separate the cornea of its natural covering, and that it is enough to cut off a portion of it in

PUPIL. When the opening in the centre of the iris is proportionately large, and this organ seems less deprived of its power of action, the disease is technically named *myopia*, which is either *accommodative* or *spasmodic*. The first form of the complaint, as Weller observes, is exemplified in cases of aphthous, hydrophthalmia, pressure on the brain from various causes, wounds, anæsthesia, &c. The second often presents itself as a paralytic affection of the iris, a state frequently induced by the application of certain narcotics, the belladonna and hyoscyamus. General cases of myopia are also met with, as well as instances brought on by long exposure to darkness. A distension of the pupil may likewise be the consequence of an affection of the retina or the motor capsule of the eye. When the retina sometimes swells, the motor-ventures produced by myopia, are intolerable of light, complete blindness is the destiny, and in the end anastrophic strabismus, occasioned by the intrusion of an inordinate quantity of the rays of light selected within the eye. The kind of myopia, and the mode of treatment, must often depend entirely upon the primary affection, of which many cases of myopia are only symptomatic. Of course, the original disorder must always be cured, if possible. When myopia appears to arise from paralysis of the iris, bladders may be applied over the eyeballs, and the same remedies used which are usually employed in other local paralytic disorders. The admission of too much light into the eye may be moderated with shades and coloured spectacles.

The case which is the reverse of the preceding is a preternaturally contracted, more or less considerable state of the pupil, termed *nyctopia*. According to Weller, it is sometimes congenital. It is often met with as a symptom of other disorders, especially aphthous, inflammation of the dura mater, pterygia, constriction of the brain, &c. Persons whose business is to be looking at small distant objects, as watchmakers, often acquire a nyctopia from habit, and they cannot be cured of it, unless they avoid the causes which brought it on, keep themselves in darkish rooms, and use a green shade or shaded spectacles.—(See *Weller's Manual*, &c. Translated by Monro, vol. 2, p. 51.) It is noticed by Beer, that myopia, and a degree of myopia, is less obnoxious than most other constrictions of ocular dilatation: for though the iris is motionless, and the pupil considerably diminished, the opening is perfectly clear and black and not drawn out of its usual position, nor its periphery edge in the slightest degree angular. The patient, though he is continually complaining of weakness of sight, is able to distinguish (with some trouble indeed) even the smallest objects in the daytime, and at very light illuminations; but his sight is extremely worse in the evening, and in darkish places in the daytime: he, when both his eyes are affected, is in the dark nearly blind, and uses severely his way. Beer remarks, that almost every considerable internal ophthalmic or iris, however favourably the disorder may be cured, and the myopia restored, always leaves after it more or less constriction of the pupil, which affection, though not the less portion of constricting myopia can be perceived in the posterior chamber, is marked with a partial or complete immobility of the iris. Beer assumes, in that every complaint which he has noticed for the permanent removal of this complaint has failed, the dilatation of the pupil was produced before but temporary. And with respect to the most powerful narcotics, he states, that at two times they were used than useless, as they caused a still greater constriction of the pupil, which, however, after a few hours, resumed its former diameter. Hence, this experienced oculist is disposed to set down the myopia following internal ophthalmia as an incurable complaint.—(See *Labor von der Augenkr.* 1. 2. p. 231, &c.)

The next case demanding some notice in this work is a disease of the pupil (termed *nyctopia*). According to Beer's observations, there is only one exception, in which in the adult patient a disease of the pupil is not the consequence of ophthalmia, and the case here specified is termed a *collyria* of the pupil, or *nyctopia pupillæ*, the causes of which are said to be, either a very considerable loss of the vitreous humor from a wound of the eye, or else a dissection of rather diminished state of the extra humor, known under the

name of *spasmodic*.—(Lieber, &c. 5. 6. p. 126.) Every internal ophthalmia, extending to the retina and choroid, when in its highest degree, it is said to produce a complete closure of the pupil. However, the obliteration of this opening is not the only cause of blindness; for long before this state of the eye happens, the sight is destroyed by considerable and frequently irreparable injury of the retina and neighbouring structures, in which the inflammation is directly situated. An inordinate closure of the pupil, Beer says, is still more disposed to take place at the period when little power from its first into its second stage, and especially (this is said to be particularly apt to occur) when in this stage the membrane becomes.—(Ibid. vol. p. 126.) In cases of the latter description, vision is not always quite recovered, but only more or less diminished, the remaining light effecting in the posterior chamber having formed only a diffuse, unaccommodated view. However, at the second stage of the inflammation, such light should be converted into a dense anæsthesia, with opacity of the lens and its capsule, the eye then only remains more or less perfect, the faculty of just distinguishing the light. But when, in such a case, the patient is completely insensible of the difference between light and darkness, the blindness, as in the examples mentioned above, is not owing to the closure of the pupil, or to the manner, but to other morbid changes resulting from the same inflammation which caused the defect in the pupil itself, and the cause of being ascertained by peculiar applications to the eye. Passing over another disease of the pupil by the unobscured matter of hyaline, and by the continuance of effused blood in the chambers of the eye, I must to the rare case noticed by Beer, in which a closure of the pupil arises from a partial dilatation of its iris to the cornea (aphthous anteriorly and vitreously) happens, when a considerable portion of the iris, or a great part of the whole of its periphery edge protrudes through an opening in the cornea, and becomes adherent to it. However, sometimes, in these cases, the pupil becomes completely obliterated, though the protrusion of the iris is inconsiderable, and its periphery edge not engaged in the cornea; a circumstance exemplified when the cornea over the adherent part of the iris extends very much, and lets an extensive, iridescent surface, so that, though the pupil may be of considerable size, it is contracted, and vision impaired. And even when there is no adhesion of the iris to the cornea, no aphthous anterior, as it is termed, and no dissection of the pupil, a large dense vitreous of the cornea may obliterate vision by being exactly over that aperture. Lastly, as Beer has explained, the cornea part of the cornea may be in an opaque, spoiled condition, so that the healthy iris can be observed only at certain points behind the cornea, so much of the pupil itself being distinguishable; and such contraction of this opening may be either continued or not, with a partial adhesion of the iris to the cornea. In such cases, the patient can frequently perceive the light very well.—(Ibid. 2. p. 124, 125.)

When what has been stated it is manifest, says Beer, that in many cases of strabismus the symptoms seem to be highly unfavorable, and that no except to Beer's artificial pupil should ever be made, when the patient's blindness proceeds from other causes besides the superficial state of the iris. Such an operation, Beer observes, can only be proper when the blindness is entirely owing to the closed or contracted state of the pupil; when the different degrees of light can be plainly distinguished; when the case is uncomplicated with any disease of other important structures of the eye, capable of rendering the surgical procedure difficult or impracticable; when the eye has been for a long time perfectly free from inflammation; when the patient is healthy, without any tendency to scrophulous, syphilitic, or gonorrheal, and both his eyes are completely blind.—(Ibid. 2. p. 126.) Some questions may be suggested respecting this artificial dilatation of the pupil, which is undeniably subject, because the line between the degrees of health and disease, suitable for the success of the operation, is difficult to specify, and gonorrhea, and scrophulous are often vague expressions. Yet, as death can ensue, I think, about the propriety of Beer's advice, never to attempt the formation of an artificial pupil, when the patient enjoys vision with one of his eyes: for when the one open,

The success of the proposal, given by Cheselden himself in the *Philosophical Transactions*, 1708, is very incomplete, and according to Mr. Guthrie, he did not actually perform the operation on the person whose history he there relates, but only succeeded in it as an effect of a particular operation which he considered worthy of record: a circumstance which, from not being attended to, has been the source of considerable error. (*Operative Surgery of the Eye*, p. 203.) Moreover, when he was at Edinburgh, now Cheselden died as an artificial pupil; but the process, as described by Howard, differs from the above, inasmuch as the needle moved as far across the posterior chamber as two-thirds of the iris, when its edge was turned towards the iris, which was then cut, and as much of it divided, as was necessary for the instrument to penetrate, as well as an artificial pupil of an oblique form.

There, perhaps, Cheselden's method, as described by Howard, is too subject to the usual one possible, but not the smallest benefit followed: for after the withdrawal of the stylus, produced by the operation, the transverse section made by the iris by the edge of the needle remained. (*Med. et Chir. Trans.*, Vol. 5, 1745, p. 147.) A failure from the same cause. (*On Operations*, chap. 29.)

An accident occurred in Paris, in the art of attaching a membrane, viz. the insertion of the iris together with the cornea, in Doyen's account, and on it perpetually, and the disease remained permanent. This led him to propose a perpendicular incision as the best expedient for making an artificial pupil. His plan consisted in opening the fornix, as is practiced for the extraction of the cataract, and in dividing the iris perpendicularly with scissors, gave that part of the pupil which is next to the cornea; did he affirm, that he has very successfully made from making the incision to make the external side, on account of the too great elevation of the optical axis.

Although the practice of making an incision in the iris or cornea is severely disapproved of by Ross, who says: "that it admits of being practiced only in very few cases, and is rendered quite unnecessary by what he denounces the two other better plans (p. 2, c. 180), it is still considered by some, and of experience as having recommendations, and the latter therefore endeavored to improve it. However, it will only be in vain to make in this work a few of its modifications.

In 1802, Sir W. Adams accomplished the revival of Cheselden's method of forming an artificial pupil, with the difference of using for the purpose a particular sort of knife. "What a singular mode (says this author) I could not cut through the iris by a gentle force, and it required to apply a greater force, the iris separated from its attachment to the ciliary ligament, which rendered all further attempts to effect a cure hopeless. The same accident appears to have happened to Mr. Sharpe at the time of this operation. In the hopes of procuring an appropriate instrument, I wrote to Dr. Lister, at the interval of a few months; but though I described in different instances, making the purpose for which it was intended, still I could not procure the needle which cuts on one edge, and the open pointed knife of different sizes, described by Cheselden. At length it occurred to me that the current edge of the current dissecting scalpel was well adapted to cut with facility. I therefore, when in London a third time, got a small knife made, two-thirds of an inch in length, and nearly a line in width, with a straight back, sharp point, and a curved edge, which cuts back towards the handle for about three lines."

(*Adams's Treat. On the Eye*, p. 203, &c.) According to this writer, it is not cases where there is no strabismus here, and the cornea is free from opacity, the position of the iris should be made in the center, and should extend across at least two-thirds of the transverse diameter. In a later work, however, he states that experience has convinced him, that so extensive a division of the iris is unnecessary for the preservation of the position of the iris, and that a fullness of one-third of its diameter is sufficient. The eye being gently fixed, either with the finger of the assistant, who supports the upper eyelid, or with a common sort of speculum placed under the upper eyelid, the artificial pupil knife is to be introduced through the center of the eye, about a line behind the iris, with the cutting edge turned backwards. The point is then

to be brought forward through the iris, somewhat more than a line from an temporary ciliary attachment, and cautiously passed through the anterior chamber, until it has nearly reached the inner edge of that membrane (as is expressed in a later description), "as it is it has traversed more than two-thirds of the width of the iris," which it should be almost immediately out of the eye, gentle pressure being made with the curved part of the cutting edge of the instrument against the iris, in the line of its transverse diameter. If in the first attempt the iris should not be sufficiently cut, the point of the knife is to be again carried forward, and similarly withdrawn, until the incision is of a proper length. After the operation, the eye is to be covered with a plaster of simple opium, and the patient put into bed, with his head raised. (P. 203, 204.) When the closure of the pupil is attended with a success, the primary steps of the operation are the same; but Sir W. Adams takes care also to cut the ciliary iris pieces, some of which he brings forward into the anterior chamber, while others he leaves in the opening of the iris, where they at first serve as a good bandage, which by the first intention (p. 205), and are afterwards absorbed. For an account of his particular method for all the various complications of cases, the reader must consult his publications, where every successful example of the operation are recorded.

That Cheselden's method ought not to be entirely rejected, there can seem to be no doubt. Like all other modes of forming an artificial pupil, it certainly does not merit exclusive preference. In addition to the brevity of Sir W. Adams, we have that of Mr. Ware, to prove that Cheselden's operation frequently succeeds. When the pupil had become closed, after an unsuccessful extraction of the cataract, Mr. Ware in several instances made a new pupil agreeably to Cheselden's mode, with the most perfect success. "The mode of the instrument as soon as they were avoided, and left the pupil very nearly of its natural size. The shape was not quite round, but the sight was immediately restored, and it is to great a degree as to enable the patient, by the help of suitable convex glasses, to see distinctly both near and distant objects, neither pain nor inflammation being consequent to the operation."

Where there is a prolapse of the iris, through a breach of the fornix, involving more or less of the pupillary margin, Mr. Travers handles Cheselden's method the most applicable; viz. "the transverse division of the stretched fibres of the iris, and which if the section is made in front of the membrane, &c. soon before backwards, admits of an improvement. The edge of the section instantly recedes and forms an excellent pupil." However, he afterwards adds, "that a partial adhesion of the pupillary margin may be combined with a nearly lost. In this case, the removal of the free border of the pupil, drawn by means of forceps through an incision in the cornea, will be preferable, on account of preserving the transparency of the lens."—(*Journal of the Diseases of the Eye*, p. 342.)

In a modern work, Professor Maunier, of Geneva, has published a very successful case, in which an artificial pupil was formed and a cataract entirely extracted. "I operated (says he) on the right eye in the following manner. The patient being seated on a chair, and having the head inclined upon a cushion, I placed myself behind him, and, with the fine finger of the left hand, holding the upper eyelid, while an assistant depressed the lower, I made with the right hand a semicircular incision at the lower and external part of the cornea. This incision occupied a full third of the circumference of the cornea. On separating the eye, the iris was seen projecting a little from the wound in the cornea. I exposed it with the blunt point of my scissors. Introducing the two blades closed into the anterior chamber, and then opening them, I caught the pupillary body; in particular for this, leaving the blunt blade between that membrane and the cornea; then drawing the scissors, a perpendicular incision of the iris resulted, extending a little more than half the chord of an arc of two-thirds of the circumference of the iris towards the side of the temple. The first incision not having succeeded the formation of a pupil of the necessary size, I introduced the same two blades a second time a little obliquely, and immediately the pupil appeared of a satisfactory form

and out, but exhibiting the crystalline convexity again. The second stroke of the surgeon had divided the capsule; I therefore introduced the second needle, in order to endeavor to destroy what adhered of the crystalline to the shock and connected circumference of the old pupil. This attempt did not succeed. Lastly, I effected a passage of a portion of the opaque lens, by means of a slight pressure with a large scoop, stretched on the lower part of the globe of the eye. The crystalline, which was of a shaggy consistency, came out with the greatest ease, and though it was not entirely removed, yet a sufficient quantity was discharged to leave the artificial pupil of a most perfect black. Wherever pupa was on the sides of the incision, and on the exterior and lower part of the iris. (See *Med. Chir. Trans.*, vol. 7, p. 360, at top.) In this communication are also two other cases, in which Mausey operated with success, though they were complicated with cataracts and adhesions of the lens to the iris. In some remarks suggested by Scarpa to the preceding account, the latter expresses his opinion, that it is not necessary to be scrupulous whether the crystalline be partly or entirely opaque, whereas the capsule is opaque and adheres to the iris behind the edge of the lens and around pupil. "In this case only incision may be got out, namely, the removal of the opaque adherent capsule, and consequently of the crystalline, whether it be transparent or opaque." In the second place (says Scarpa), I think there is no reason to believe, that in similar cases, it is advisable to make an incision upon the iris, proportioned to the size of the body to be extracted, rather than to make it small, which shapes the operation to destroy the crystalline and the capsule, with the intention of extracting a part and of substituting the rest to the power of absorption. Thirdly, I would establish as a fundamental principle, in similar cases, that after the complete extraction of the crystalline, with its opaque capsule, by means of the least possible introduction of the instrument, the artificial pupil ought not to be too near the incision in the cornea, and consequently not too near the incision suggested by it." (P. 367.) Scarpa then recommends a particular method of operating in cases where there are cataracts: after having made, in the manner of Wenzel, a transverse incision in the iris and in the cornea, he would introduce Mausey's scoops, placed at both points, into the anterior chamber of the opaque lens, and make an incision in the iris, diverging from the cut made with the knife. The aperture thus made, Scarpa thinks, would be large enough for the easy passage of the opaque lens.

Among other late opinions professed by Scarpa, we find the following: that no instrument is so proper as the scoops for making an incision in the iris; and when the case is not complicated by cataract, a very small wound in the cornea is sufficient; also the situation of a triangular edge in the iris, by means of a double incision with the scissors, is the most easy and least painful of all the methods hitherto proposed for obtaining a permanent artificial pupil; and, lastly, that, shortly after the cornea, present no obstacle, because the artificial pupil may be made opposite the transparent part of that membrane. (See *Med. Chir. Trans.*, vol. 7, p. 331, 332.)

As I have already noticed, the contraction of the natural pupil is sometimes occasioned by the iris being stretched towards some point of the cornea towards which it is adhered. This state, as Scarpa observes, is most frequently accompanied with unequal opacity of the iris, arising from the adhesion, or depression of the iris, as well as with equality of the lens and its capsule. At other times, however, these beyond parts preserve their natural transparency, notwithstanding the contraction of the natural pupil. In the latter case, the pupil, though enlarged from its dilatation, is not so fully dilated, but merely very much contracted, and incapable of admitting the quantity of light necessary for vision, especially if the opposite part of the cornea be slightly convex. In such an example, Scarpa recommends making a small incision in the cornea to the most transparent part, even with Mausey's scoops drawn down, and connected with life before it is made to break the adhesion existing between the iris and the cornea. If this can be effected, the natural pupil generally recovers its former situation and size; but if the distance be very firm, Scarpa instructs us

of the blades within the contracted pupil, behind the posterior lamella of the iris, first the other blade has inserted the point of the corner with the sclerotic. The iris is then to be divided in one form of the letter Y, without at all tearing the capsule or lens, both of which are transparent. (See *Diagnosis of the Eye*, p. 264, at 2, transit, by Scarpa.) When, after extraction of the cataract, the pupil has been drawn down in this manner by adhesion to the lower part of the cornea, the upper two-thirds of which are transparent, Dr. Mausey, of Glasgow, has succeeded by drawing to form an artificial pupil, and removing vision, by making a small opening in the lower and outer part of the edge of the cornea, opposite to admitting Mausey's scoops, with which the contracted blade of the iris are to be cut down by a simple incision, these lines to length. The iris thus successively divides and leaves out paper of softening wire. (See *Wells's Manual*, vol. 2, p. 10.) In the cases above specified by Scarpa, Dr. Wm. Aitken, in view of performing cataract, endeavors to separate the iris from the cornea, and then to alter the position of the pupil by drawing it towards that part of the cornea, which has remained transparent. For this purpose he punctures the cornea above and below the base of the iris, separates the adhesion, and then makes the disengaged portion of the iris pass through the puncture and leaves it there, even upon the sclera, if necessary, forwarding it out as far as it is deemed necessary for its being securely fixed. This method is disapproved by Scarpa, because a small portion of the iris in the same eye, appears to have a very serious disease, and rather calculated to increase the opacity of the cornea, and diminish the contraction of the pupil, than a good effect.

According to Beer, in the removal of a portion of the iris, cataract is particularly indicated in all cases in which there is a small transparent area, as in many examples of syphilitic disease, considered as the natural pupil by a central opacity of the cornea. Beer advises, however, as an exception, the cataract, which the transparent portion of the cornea is so small that an opening can be made in it with the best success, enough to permit the iris to be taken out or with a small hook or forceps, and a piece of it cut out about the ciliary processes. (P. 3, p. 209.) The reason Beer gives does not appear to myself very strong, because may be asked, why not require more room by cutting a portion of the opaque part of the cornea? What means a better reason against cataract, etc. than its refers to the risk of a second piece of the cornea not being left transparent, opposite the new pupil, and the contraction of that membrane. (P. 2, p. 21.) Beer likewise states, that cataract may be performed in cases of atresia of the cornea, in the manner of extracting the cataract, when the pupil is small, that an oblique pupil, formed during the disease, inflammation in the posterior chamber, and the more the lower edge of the cornea, or is exposed with some of the remaining capsule of the iris. The last case may be derived from the singular nature and form of the greater part of the iris; the wound, from the very indistinct manner in which the pupil is made of the different degrees of light. (P. 3, p. 208.)

The creation of a space of the iris, says Beer, requires the preliminary formation of a hole in the cornea one line in length, with the corner of the eye, and as far as possible in the sclerotic, as told in common, the opaque cornea may derive with the removal of the operation. The second part of the operation, the extraction of a piece of the iris, must be done in three ways, according to circumstances. 1. The iris may be cut by any where adherent to the cornea, in which case, after an opening has been made in the iris, the cornea, the iris is pushed out, through the edge of the wound by the second instrument, and left in the posterior chamber, which, apparently, the cornea immediately avails himself of to form the pupil of the projecting piece of the iris with a very fine hook, and cut it off with Beer's scissors. The remainder of the iris is internally retained behind the cornea, and a well-formed pupil is immediately seen. 2. Only the part of the edge of the pupil was drawn out adherent to and drawn through the cornea, when it is needed to form the artificial pupil; a wire is introduced by a lateral incision of the eye. Some time, after opening the cornea, then says, the operation

is directly to introduce a small hook between the iris and cornea, as is best to insert either of these parts with the point, and be it then, with the instrument directed obliquely, to go behind the pupillary edge of the iris, and, while the eye is drawn out between the edges of the incision, the grasping force is to be cut off with Davy's scissors. This artificial pupil is then extended behind the transparent part of the cornea towards the edge of this membrane. 2. The pupillary edge of the iris may be adherent to the cornea entirely in the situation where the artificial pupil is to be formed. In this case, then, directs the eye to be taken hold of at its greater convex with the hook, or (if this should fear its way) only with a pair of fine-pointed forceps, with both fingers set between the edges of the wound, and the point of the cornea thus provided cut off somewhat within the edges of the wound, as directing the iris further out might fear it and have a prejudicial effect. In all these cases, says Best, the undivided lens and vitreous will not be injured if the patient keep tolerably steady, and the operator have already acquired facility in the extraction of the cataract. The operation being finished, the subsequent treatment is like that generally adopted after the extraction of the cataract.—(See Cataract.) When cataracts are so performed in a closure of the pupil, consequent to removal of the cataract, Best particularly recommends the forceps to be used, though he adds, that such operation is applicable only when the remaining capsule has not been spoiled by inflammation, and the quantity of humor in the posterior chamber is not so great as to reach above the lower part of the eye.

The only other species of cataracts which I deem it necessary to notice, is what was proposed, in the year 1811, by the late Mr. Gibson of Manchester. It is described as follows:—The first object of the operation is to incise the eyeball, as in the operation for cataract, supra cataract. A puncture is then to be made in the cornea, with a broad cornea-knife, within a line of the limbus, to the extent of about three lines. As pressure is now to be removed from the eyeball, and the cornea-knife partly withdrawn. The consequence of this is, that a portion of the aqueous humor escapes, and the vitreous body comes in contact with the opening from whence it came, and closes it like a valve. A slight pressure may now be made upon the superior and nasal part of the eyeball, with the first and middle finger of the left hand, till at length, by an occasional increase of pressure, or by varying its direction, the iris gradually protrudes, so as to present a bag of the size of a large pea's head. This protruded portion must be cut off with a pair of fine curved scissors, and all pressure at the same time removed: the iris will then recede within the eye, and the portion which has been removed will leave an artificial pupil more or less circular.—(Gibson on Artificial Pupil, &c. Lond. 1811.) Such was this surgeon's mode of operating, when the convex of the pupil was attended with central opacity of the cornea, unobscured with adhesions. The effect of a slight adhesion of the lower border of the iris to the cornea will be, to prevent the protrusion of the first of these membranes through the aperture in the cornea, which protrudes as much facilitates the operation. In this case, a portion which does not adhere must be drawn out with a small hook, and then removed. Sometimes the adhesion may be separated at the time of making the puncture, and then the iris will protrude. When the whole or greater part of the lower border of the iris is involved in adhesions to the cornea, there must be separated with the cornea-knife when making the puncture, and the iris may thereafter be drawn out with the hook, in a degree of it be removed by means of very minute scissors. In every case, however, the removal of a portion is essential to success.

When a cataract is known to exist, Mr. Gibson recommends it to be depressed, or broken to pieces with the knife, before making the artificial pupil; and when the whole cornea is transparent, he directs a flap to be made in the centre of the iris with the cornea-knife, and then cut off with the long scissors.—(Gibson, op. cit.)

Coronoiditis, or the mode of forming an artificial pupil by drawing a portion of the iris from the ciliary ligament, is said to have been devised by A. Schmidt and Scarpa about the same time, and has been suc-

cessfully modified by Bismuth, Linsenbock, Hing, Graefe, and others.—(Waller on Diseases of the Eye, vol. 2, p. 85.) According to Bismuth, this mode of operating is indicated, first, only when the remaining ligament, effused in the posterior chamber after the extraction of the cataract, or reticulation (see this word), reaches five or six above the lower arch of the iris towards the ciliary processes; a circumstance which may be known by the considerable change of colour in the greater circle of the iris, and by the indistinct manner in which the pupil perceives the light. Secondly, when the iris is every where adherent to a remaining capsular connective, or capsular lenticular cataract, or the closure of the pupil has been occasioned by a patient or bloody contact. Whenever the attempt is made in these last cases, however, the patient should be capable, as far as possible, of plainly observing the light. Lastly, coronoiditis is indicated by Best, when the bottom is every where intimately opaque, excepting of small part of it, if this it could not well be used for the exposure of a portion of the iris.—(Id. p. 102.)

When the closed pupil is the result of inflammation from an injury, the lens has been absorbed, and the vitreous capsule, or both the anterior and posterior, are thickened and firmly adhered to the iris with only an indistinct perception of light, and a discoloration of the lower circle of the iris, indicating a deposition of lymph behind it, Mr. Graefe was doing coronoiditis as the proper operation. After the formation of a triangular opening by the scissors should not be easily accomplished as a sufficient remedy; and the simple extraction of the central part of the iris would be general be sufficient, in consequence of the thickened capsule preventing the necessary contraction of the fibres of the iris.—(Operative Surgery of the Eye, p. 466.)

The first motion of the iris towards the ciliary ligament, and consequently the greater facility of detaching the edge from this ligament, with which it is connected, that of liberating the body, which Scarpa to try a few moments of stirring an artificial pupil when the natural one had become too much contracted, or quite obliterated, after the extraction or depression of the cataract. His method of operating consists in depressing by means of a searching needle, a corner extent of the circumference of the iris from the ciliary ligament, without dividing the corner. The attempt must with success.

The patient being reclined and supported, so if he were about to have the operation for the cataract performed, a straight slender searching needle is to be introduced through the sclerotic, at the external angle of the eye, about two lines from the margin of this membrane with the cornea; and the point is to be pushed as far as the upper and inner edge of the iris: in other words, as far as that side of the iris which is nearest the nose. The needle advances nearly to the ciliary ligament, and the surgeon perforates the internal edge of the iris at its upper part, so that the point of the instrument entirely appears in the anterior chamber, because that part of it is very narrow, the point of the instrument, however little it advances beyond the iris, would enter the substance of the cornea. The narrow needle appears in the anterior chamber, the instrument may be pressed on the iris from above downwards, and from the internal towards the external angle, so as to bring it in a parallel line to the anterior surface of the iris, for the purpose of detaching a portion of the edge of this membrane from the ciliary ligament. This operation being effected, the operator must depress the point of the needle, in order to apply it to the inferior angle of the iris that he has begun to separate. Then the aperture may be enlarged at pleasure by pushing the iris towards the temple, and withdrawing the needle from before backwards, parallel to the internal surface of the iris and the greatest part of the eye. If, when this detachment has been accomplished, no opaque body appears at the bottom of the eye, the needle is to be withdrawn altogether. In any portion of opaque capsule left behind after the depression or extraction of the cataract should attending adhesions and prevent itself in the vicinity of the pupil, the little opaque membrane must be ordered to be drawn, and pushed through the artificial opening into the anterior chamber, where, Scarpa says, they will be found and absorbed.

This separation of the iris from the ciliary ligament necessarily occasions an extravasation of blood, which

Q

QUININE, SULPHATE OF. This valuable preparation of bark, which is now beginning to be prescribed in a large number of malarial cases where fever is ague-like and general debility the poorest, may be exhibited in doses of from half a grain, three or four times a day, according to circumstances. As its utility is made to increase by an exposure of cold, one drop of sulphuric acid is frequently added for every grain of quinine. When, however, the circumstances of the case

render it advisable to dispense with the acid, the sal-
place of quinine may be prescribed instead if in any
aromatic water, like the *agua carra*, or in the form of
pills, either by itself or combined with opium, like pill,
quinine, the aromatic cone, or such other medicines as
circumstances may require. It may also be given to
children, mixed with syrup. Other preparations are
the wine and tincture.

R

RACHITIS. From *ráxu*, the spine of the back. Because the disease was once supposed to depend on disease of the spinal marrow. The jacks. See this word.

MANULA. (Dist. of yoma, a frog.) A toadster under the tongue, making from an accumulation of saliva and mucus in the ducts of the sublingual gland. The term has been derived either from an imaginary resemblance of the swelling to a frog, or from the disease making the patient, as it were, croak when he attempts to articulate. Many writers as have treated of this disease, before it was known that the tumor affected is more destined for the secretion of the saliva, could have no accurate notion of its true nature. Others it supposed to have issued to the muscle, in the fork between the seventh tooth, where, after tearing of the diamus of the tongue, he introduced the following passage, and lived *perpetuo interius adque* *sancti, quod per os eunt in tunc, delinquit iniquiter* *monet.* The latter assumption, however, is not probable, that some other affection was signified, as a tumor merely attended with a *series of events*, that is, pain. Fabricius at Squamensis and Dionis considered it exactly as an *inverted* tumor of the tonsil-like kind. Mead, better acquainted with the modern discoveries of anatomy, does not mistake the nature of the present disease; and he expressly says, that the affection originates from a thick saliva, which, not being able to pass out of the salivary ducts, accumulates under the tongue, so as to cause a swelling in that situation. Far from adopting the opinion of Mead, however, he took to that of Fabricius, and borrowed every thing from that author. Linnæ, de in Pains, in his notes on Dionis, adopted Mead's sentiments, he says, "There are two sorts of *Manula*, some, which are bound, and raised beneath the tongue, seem only to be produced by a distention of the secretory duct of the sublingual gland; the others are looser than they are round, are situated at the side of the tongue, and are formed by a distention of the excretory duct of the la-

Grass maturing grass. The field which this year is
mowed is the same, which gradually accumulates in
them, is a consequence of its vocation and the way of
the day.

Persons who serve their masters a great deal, and those who say, have been set down as very pliant to the present capitalist. But this opinion, I believe, rests on no good foundation. The flaw in the argument is precisely the whole of it; but it thickens after having remained a long while in the mind, and it is consequently a calumnious, and even slandering, insinuation. Karla does not proceed from an insubordination of the mind, as De la Paro supposed, but from an obstruction on the part of others of this mind. The capitalist often produces a thimble of very large size; but the working generally insists when it has attained the dimensions of a walnut, and then leaves us alone which cannot be denied. While the real cause of the disaster remains unknown.

Mr. E. Ball saw as also of this kind, which was made with the slogan that the survival instincts of the organism and economic applications were employed, and even a memorial column that all in vain. At length the true cause of the disease having been ascertained, a cure was accomplished in a few days by removing a piece of calcareous matter, which, by obstructing the ducts, had first caused the swelling and then ulceration.

The opening, when made with a laser, and not of sufficient size, frequently closes again. In this case, the prevailing response was days afterward. The aneurysm made the same twinkle - and hence, Park performed the actual surgery to the laser. Blood had also been under control, after they had been simply opened with a laser, and he was confident, for the avoidance of this inconvenience, the implications of a mixture of lakes of iron and sulphur, as well as the nature of the eye, so as to destroy it. As Louis remarks, all artists seem to agree that the sensation of the landscape should be the one he has been able

a strumous pustule after the eruption of a chancre; but he continued long after every remaining abscess.—(*Ann. Med. et Chirurg. Lond.* t. 60, p. 234.) The commentators, Mr. Guallard, illuminated himself several years with the discharge from strumous sores and abscesses, and the result was, that the disease could not be thus transmitted.—(*the Principles of the Practice and Theory of the Venereal System*, p. 121.)

The parts which are most frequently affected by scrofula, next to the lymphatic glands, and perhaps the skin, are the osseous fields of the bones and the joints. The first article the strumous disease is the latter parts is particularly discussed in the article *Joint*. The disease of the spine attended with a parasitic affection of the lower extremities, is, in itself, very frequently of scrofulous origin.—(*see Testicles*.) *Spina* holds a prominent place, and is especially seen in children, whose parents are strumous.—(*Thomson's Lectures*, p. 135.) The strumous which arises in the cellular substance, between the peritoneum and pleura, is often regarded as a strumous disease, and when the contents of the abscess are found to consist of a watery matter, somewhat resembling white of egg, a scrofulous peritonitis or pleuritis is diagnosed; but we can doubt that the complaint is concerned with this constitutional affection.—(*see Abscess of Pleura*.) The disease which arises in the thyroid gland is sometimes considered as scrofulous; but, though patients with this affection, very often live, at the same time, other constitutions, which are manifestly strumous, though the enlargement of the thyroid gland most frequently commences in an early period of life, like scrofulous disease, and though the tumor is sometimes limited by the capsule of the gland, and is sometimes, and indeed, the commonest, is either in the cellular—(*see Testicles*.) Scrofula also frequently makes its appearance in the form of enlarged appendages, in various parts of the body; the contents of such abscesses being a kind like matter, and the skin covering them being so indurated and appressed, and a thickened double fold. The strumous glands are often found universally diseased and enlarged in scrofulous subjects, and, as all discharges had to pass through these parts, before it can arrive in the circulation, we cannot be surprised, at the many ill effects which must be produced on the system, whenever glands are thus diseased. However, as I have already hinted, I have not established, by Dr. Rossignol, whether enlarged testicular glands are decidedly scrofulous; but if he is correct in his assertion, I fear he has been led to adopt it by his particular theory, which limits the origin of scrofula to the superficial absorbent glands. Scrofula frequently takes its attack on the testicles.—(*see Testicles, Diseases of*.) The female breast is also subject to scrofulous tumours and abscesses.

According to Mr. A. Cooper, scrofulous persons frequently have fistulas in different parts of the body, incrustated with inspissated matter. He agrees with most other writers in considering the absorbent glands and joints as the parts most frequently attacked, especially the glands of the neck and axillary. Various other parts of the body are enumerated as liable to it—the lungs, the brain, the eyes; but the heart, he believes, is never affected. The sweating glands, he also says, are rarely the seat of scrofula, as does the liver and kidneys; for the breast and testicles are exceptions.

Dr. Thomson believes, that some or less local inflammation occurs in every form and stage of scrofulous disease. He observes, that the swellings are very often the first thing attended with a sensible increase of heat and redness, and then the pain, though seldom acute, is always present in a greater or less degree. Pressure on scrofulous swellings never fails to excite pain; and the temperature of the skin covering them, is nearly even in these degrees higher than that of the contiguous parts.—(*Lectures*, &c. p. 111.)

Scrofulous inflammation, as Mr. John Harris observes is marked by a red swelling of the affected part, which very frequently is one of the lymphatic glands. The covering of the gland becomes greatly thickened, and its substance more porous and spongy. The swelling increases, and the discharge, first changes by degrees into that of pus, or inflammation, and is then characterized, by a thick margin, and is not usual till late in the disease. The skin is slightly red. At this time, an abscess or pimple is made, either on matter or very little contained;

the top of the wound opens, and opens, displaying a bloody-looking substance within; and between this and the skin a probe can often be introduced for some way at least. It, however, the disease should have advanced farther, this, there is very little elasticity in the tissue; it is white, not, rather blood, and decolorizes slowly; the skin becomes of a light purple colour, and small veins may be seen ramifying on its surface. Some time after these appearances, the skin becomes thicker in one particular part, and here it is also generally reddened of a darker colour. It afterward bursts, and discharges its fluid, like pus, mixed with a curdy matter, or thick white fluxion. The colour of the skin still continues; but the absorbent relations of the cancer subsiding, and thus a scrofulous stage is pursued. The margins of this kind of sore are generally smooth, obtuse, and overlap the skin; they are of a purple colour, and rather hard and raised. The surface of the sore is of a light color; the granulations are thick and indurated, and the matter is of a peculiar kind, which, says Mr. Harris, cannot be described. The discharge is thin, slightlyropy, and copious, with curdy flakes. The pain is insupportable. When the skin has continued for some time, it either begins slowly to exfoliate, or, as more frequently happens, the discharge diminishes and becomes thicker. An elevated edge is next formed, of a dirty white or redish color. This continues on the part a solid wall, and when it falls off, leaves the place covered with a small purple crust. Mr. Harris adds, that the preceding description corresponds to the old scrofula, or the strumous mamma of the old writers. Sometimes, especially if a large tumour below the axilla, the sore has a more bony appearance, the surface is dark-colored, the edges are soft, elevated, and inflamed, and sometimes spitted. The discharge is watery, the pain very considerable, and the surrounding skin is inflamed. This has been called the strumous melanosis. Such suppurating scrofulous parts are most frequently met with near the axilla; parts, particularly those of the nose. Sometimes a scrofulous chancre arises in the breast, first in matter, the breast of which abscesses, and assumes the specific scrofulous appearance, with the neck of the same still continuing to emit its discharge. Scrofulous swellings are often disposed to subside in winter, and recur on the approach of summer; but this is not an invariable law. Glandular enlargements are very apt to become smaller, in a short time, in some places, while others grow more extensive with equal indolence, notwithstanding the vicinity of the former ones. Ulcers also very often heal upon the appearance of the disease in other parts.—(*Baron's Dissertation on Inflammation*, vol. 2, 1802.)

The glandular swellings which occur in scrofula, says Dr. Thomson, are of a more acute character than those which proceed from scrofula. They arise from the absorption of a specific poison; and they do not, like those of scrofula, admit of a spontaneous cure; a better, however, may however not to be exactly correct.—(*see External Diseases*.) Glandular enlargements of the lymphatic absorbent glands occur also in cancerous; but these manifest little or no disposition to suppuration; they survive most frequently to considerable induration, or ulcers existing in the neighborhood of the glands affected; and they are accompanied in their progress and growth by a peculiar fluctuating pain.—(*the Inflammation*, p. 125.)

With regard to the particular cause of scrofula, several men may be said to discuss, even at the present day, in entire ignorance of it. After the education theory, besides scrofula to certain humors in the constitution, or diseased stages in the blood, had been exploded, the opinion gradually arose, that it was a disease of the lymphatic system; and indeed, that the discharging glands are often entirely the seat of its attack, when no changes are distinguishable in other parts; it is a fact that admits of no dispute. Besides, at the same time, that wherever discharges scrofula are extensively issued to the lymphatic system, must have a very imperfect conception of what is really the case. On the contrary, I fully participate in the sentiments of Professor Thomson, already adduced upon this point, but in the belief of modern medical writers, that strumous inflammations "are not to be considered as dependent on disease of any particular system, as the lymphatic."—(*Lectures*, p. 101.) But

written as have fitted upon the slightest vessels as the particular seat of scrofula, can throw no useful light upon its origin, by following up the theory, whether they imagine the cause to be disturbance of the vessels and glands, or take to the wild speculation of Calani, that in scrofula the vessels of the lymphatics are in a state of increased activity, while the vessels themselves are in a state of atony; or the doctrine of Bouchardet, that scrofula depends upon a passive plethora and debility of the vessels; or the hypothesis of Girtanner, that these vessels are in a state of increased irritability. The idea of disturbance being the cause has of late years been much on the decline; and that the involvement of lymphatic vessels forming the glands the acute perfora, and may readily be rejected, even when deemed, is a fact first demonstrated by Serres, which again would heavily against this opinion. Sir A. Cooper describes the disease as proceeding from congested activity, which attacks the whole course, and imparts to it a peculiar character, rendering the various processes of inflammation in it slow and imperfect.—(Lancet, vol. 3, p. 65.) Of the exciting causes, very little is known. Mr. John Hunter remarks, that it is frequently the tendency to scrofula arises from the climate, which is in many a predisposing cause, and only requires some disturbance to become an immediate cause, and produce the whole disease.—(On the Venereal Disease, p. 25.) The disease is considered to be most common in females; in cold, damp, marshy countries, and in all places, more high mountains, where the temperature is subject to great vicissitudes.—Some voyagers remark, that it is more common in the interior of the island, or towards the mountains, than in the coast.—(Voyage de la Recherche, p. 418.)

In the work cited the last last year, Mr. Hunter takes notice of slight fevers, colds, small-pox, and measles, creating scrofulous disease. He observes, that in particular countries, and in young people, there are sometimes a predisposition to scrofula; and that in such subjects, badness will more readily become scrofulous.—(P. 22.) In short, it was one of Mr. Hunter's opinions, that the venereal disease is capable of calling into action such predispositions as are remarkably strong, and peculiar to certain constitutions and countries; and that, as scrofula is predominant in this country, some effects of other diseases may partake of a scrofulous nature.—(P. 36.) Mr. Hunter, speaking of venereal disease, sometimes has having long suspected a scrofulous cause, and adds, "I am now certain that such cases. I have seen cases where the venereal matter, like a cold, or fever, has only invaded the glands in disease, producing in them scrofula, to which they were predisposed." In such cases, the scrofulous tendency more slowly, give but little pain, and seems to be rather increased in their progress; if mercury is given to destroy the venereal disposition. Some cases of scrofula while under this venereal course; and others, which probably had a venereal taint at first, become so tedious that mercury has no effect upon them; and, in the end, they get well of themselves, or by other means.—(P. 208.) For such diseases, Mr. Hunter used to recommend sweating; and, in case of suppuration, poultices made of sea-water.

Sir A. Cooper observes, that the scrofulous cause of scrofula is composed, in original form, of condensation. The exciting causes, he says, are whatever leads to produce or increase debility, such as fever from disease of a specific kind, the measles, scarlet fever, and small-pox. He notices the greater frequency on this account of scrofulous cases some years ago, when the advantages of vaccination were less known; and the importance of this point to society, if it had no other recommendation.—(See Lancet, vol. 3, p. 78.)

In the words of a well-spared Professor, scrofula readily forms its alliance with almost every kind of affection, occurring either from external injury, or from internal disease; it modifies the appearance of some diseases, and seems to convert others gradually into its own nature. Indeed, there are few of the acute inflammatory affections which occur in this country, in which the symptoms and effects of these affections, and the operation of the feed and remedies employed for their cure, are not more or less modified by the degree of scrofulous disposition, which prevails in the constitution of those who are affected by them.—The

scrofulous disposition, whenever it exists, usually gives more or less of a chronic character to local inflammatory affections.—(Thomson's Lectures, p. 111.)

Docteurin's correspondence to make of scrofulous disease, as defined by Dr. Astruc, "The case," says he, "which seems most obscure, is that the connection of the scrofulous habit with various debilitating causes, may be regarded as follows.—1. The difference in the symptoms and progress of inflammation, when scrofulous, and when healthy, tends to indicate in the former case a larger mass of the stimulus, particularly in the capillary vessels of the diseased part. 2. The scrofulous disposition to scrofula is chiefly transmitted from parents, and is mostly observed in the low, rich, slow, robust, and constitutional delicacy in either sex. 3. There is no state of the body, or every particular known, in which scrofulous action is less easily excited, as the state of great and often permanent fever, which is usually after severe febrile disease, continued long, small-pox, measles, scarlet, or which follows the long-continued use of mercury, as atropine, and mercury. 4. The season in which scrofulous disease has been observed to prevail most in this country, is not that when cold weather has recently set in, and is most productive of disease in general, but the end of the winter and the spring; and they are most easily observed in those young persons who have been in the country, during the continuance of the cold season."—(Lectures on the Med. and Phys. of the Human Body, vol. 3, p. 381.)

It has been the fashion of late years to trace the origin of a great number of diseases to disorder of the digestive organs, little trouble being generally taken to consider, with any regularity, whether the disorder of those organs may not be taken for another effect than the common cause of so many various diseases.

Numerous circumstances tend to persuade the doctor into such a view, particularly one which upon this topic. They are various, I mean, attended with dyspepsia, flatulence, loss of appetite, constipation, and a torpid state of the bowels; they denote that such diseases and the latter complaint of the digestive canal generally derange the health, and, as the functions of the stomach and bowels are deranged, any other disease which the patient may be subject to, either grow worse, or be retarded in its cure; and, lastly, the treatment, in which the theory leads, improves the health, by restoring the state of the digestive canal; and the use of opium, or other cramp, in the end, with the subsequent use of food, exercise, and other favorable circumstances, goes well. But, however simple, safe, and much to be prescribed, it is, and just as the theory which leads to it, there is no proof that the other disease was truly a consequence of the disorder of the digestive organs. The latter symptoms, I believe, in very few cases, no effect whatever for a cure, and perhaps always in its relation to scrofula. Besides, if it were so, it is common (as indeed it actually is), that in scrofulous diseases there is more or less disorder of the digestive organs; but primarily of another important function. I do not see that the advance can stop beyond the truth; because, as the more there is generally proved to be given attacked to this theory, for a new variety of other cases, we can readily see in the dark it is the circumstances which make so ready comparison of different kinds spring from one and the same thing. These circumstances, though hard to detect, being the mystery—until the secret, which is known, and it is known and that the effect is all very happy in particular constitutions, then we are brought back to the position from which we first started. We are thus brought to a disease depending upon some cause, the possibility of recognition, comparative standard, and the points of being excited into action by some cause, or climate, mode of living, &c. However, now I will not have attached sufficient importance to the disturbance of the digestive organs being the cause of scrofula, I feel pleasure in referring for the acquaintance to my part, to the writings of Mr. Abernethy, Dr. Cullen, and Mr. Lloyd, whose treatment appears highly commendable so far as they used to treat scrofula. There is great confidence in various salutary means to improve the health in general, as the most likely mode of having long scrofulous patients, than to encourage such means almost new specifics for the disease. The

far I can follow these gentlemen safely, but no farther, except in a skeptic. However, perhaps some of the believers in the effect of disorder of the digestive system might say, that such disorder is any thing more than one of the many exciting causes of scrofula; and with this qualification their theory may at least not be incorrect. It is the doctrine of Alibert, and instead of merely all systems: "Ce n'est pas le vice de la pureté sanguine, qui prépare le terrain à la scrofule. Il n'est pas davantage son seul développement qui la manifeste, qu'elle lui résiste." &c.—(Nouvel. Nomenclature, p. 418.) "Aliment et air n'ont pas plus les scrofuleux malades." But every explanation, even of curative failures, remains unsatisfactory, so long as we find children living in the same air, under the same roof, and feeding and sleeping together, and clothed identically alike, yet only one or two of them become scrofulous, while all the rest continue perfectly free from the disease. Here, then, we are again compelled to return to predisposition, constitution, climate, and an occasional tendency to the complaint, as a solution of the difficulty. In short, then, respecting the etiology of scrofula little is known, except that certain constitutions probably have a congenital disposition to the disease; that such disposition may be increased or diminished by the operation of climate, mode of life, age, &c.; and that treatment of a threatened kind may avert the disease into action, unless the system is predisposed to it, by inoperable causes. That climate has great influence cannot be doubted, when it is reflected, that the inhabitants of certain countries, in which the temperature is unusually warm, never suffer from scrofula. It is noticed by Sir A. Cooper, that the occurrence of scrofulous swellings promoted by climates, in which the change from cold to heat, and from land to sea-breeze, is particularly frequent, is in the case of this island. But though cold and wet summer lasts this effect, he remarks little progress being in the experience of heat or cold are not affected. The disease, he says, is more common by cold and land, uncombined with a damp atmosphere. On the other hand, numerous children now come from the East or West Indies to this country full a prey to scrofula. He has also known some individuals from the South Sea Islands die of the same disease.—(Lancet, vol. 4, p. 67, 68.) The fact of the great influence of climate on scrofula is equally proved by the effect of the summer and winter, for it is a common and a true remark, that in a mild dry atmosphere, and in summer time, the health of scrofulous persons generally improves, and whatever local complaints they may have get better, while in the contrary winter disorder in winter is more difficult of relief, and either continues stationary, or becomes worse again. Hence, on Sir A. Cooper has justly remarked, the exact value of any proposed remedy for scrofula cannot be estimated, without reference to the time of year when it is tried. There can also be no doubt that, with age, the disposition to scrofula diminishes; for children, much afflicted while young, frequently get quite well when they approach the adult state; and if a person remains perfectly free from every mark of a scrofulous constitution till the age of twenty-five, he may be considered as nearly out of all danger of the disease.

According to the calculations of Dr. Alison, scrofulous diseases are much more frequent in the inhabitants of great towns than in the agricultural population of his country. This seems to him an unquestionable fact, and one that confirms the truth of the connection of scrofula with debilitated cases.—(See Edinb. Med. Clin. Trans. vol. 1, p. 252.)

TREATMENT OF SCROFULA.

"For the cure of scrofula," says Gulliver, "we have not yet learned any practice that is certainly or even probably successful. The remedy which seems to be the most successful, and which can justify us especially as to its use, is the use of mineral waters. But, he adds, in very heavy instances of the use of these waters, I have not been much satisfied that they had shortened the duration of the disease more than had other disordered when we such remedy had been employed. With regard to the choice of the mineral waters, none fit for the purpose, I cannot, with any confidence, give an opinion. Almost all kinds of mineral waters, whether chalybeate, sulphureous, or saline have been employed for the cure of scrofula, and

sometimes with equal success and reputation; a circumstance which leads me to think, that if they are ever successful, it is the stimulatory power that is the chief part of the remedy. Of these, iron-waters have been especially recommended, and employed; but when I am candid, I cannot yet discover its superior efficacy."—(First Treatise of Physic, vol. 4.) On the subject of mineral waters, Dr. Thomson very properly remarks, that they are more usually employed as purgatives and tonic remedies, and not as specifics. In employing them it is often difficult to distinguish between the effects which they really produce, and those which are to be attributed to the slow operation of time, the season of the year, change of situation, variation in the mode of life, or exercise in the open air.—(Lectures on Hygiene, &c. p. 183.)

In scrofulous diseases, Dr. Pottger had a high opinion of bark; and he recommended to prove, that in cases of tubercular glands affected with a tubercle, but not a weak stimulation, it is a most efficacious remedy, and only as a remedy and stimulant. He also holds forward a certain support of bark being a source of cure for scrofulous diseases.—(See Med. Obs. and Inq. vol. 1, p. 185.) Dr. Pottger, in the same work, p. 263, writes in favor of the good effects of bark in similar cases, "scrofulous of tubercle being sometimes given with it."

Dr. Cullen considered the efficacy of bark in scrofulous eruptions and tumors.—(First Lines, &c. vol. 4.)

According to Mr. Harris, bark has been frequently found useful in the cure of scrofulous inflammation, but more often of inflammation than transudation of the glands. Thus, says he, it does not appear to promote, by any remedy, that certain power of causing scrofulous affections, which is attributed to it by Dr. Pottger and several other authors. He observes, that we are not to suppose it will infallibly cure scrofulous inflammation, or tubercles of parts, which, even when affected with simple inflammation, are very difficult of cure. If it be shown to cure a simple inflammation or tubercle of a tendon, cartilage, or bone, we must not be disappointed if even a specific remedy for scrofula were such over-discovered, should prove imperfect in producing a speedy resolution in health. Mr. Harris remarks that bark is often inefficient, because in properly administered. Given in such quantities, once or twice a day, it may prove a stimulant, and increase, too often tonic before, the power of the stomach, or the functions dependent on it; but in order to obtain the benefits of the specific action of bark, he maintains that it should be given in large quantities, for several weeks, with a good diet, air, and proper exercise.—(On Inflammation, vol. 2, p. 373.) Dr. Thomson does not believe that bark or iron has any specific virtue in curing scrofula; but he obtains more either of these remedies and sometimes prove useful in lessening the heat of the digestive organs, when given alone, or occasionally about meals, a course of purgative mineral waters.—(Lectures, p. 277.) When bark is prescribed, the substance of Gulliver is one of the best formulae, as best likely to disagree with the stomach.

As far as I can judge, Mr. White has with much reason recommended paying attention to such circumstances as may have effect in preventing the disease, viz. air, diet, exercise, and dirt. He mentions cold bathing, among the preventives of scrofula, and speaks of sea-bathing as being the best. The chief attention also to be paid to the manner of clothing children, keeping them bare covered in winter than summer. He thought a great deal of sleep beneficial, but this seems only conjecture.

In noticing the treatment of the disease, Mr. White states, that "the present idea of the disease is, that it is a disease of debility (a disease also mentioned by Sir A. Cooper), and therefore, the great object is to invigorate the habit by every possible means; the chief of which are tonic medicines, and sea-bathing. Some are of opinion, that in the case of young persons, this should be continued during the summer months, every year, to the age of fourteen or sixteen. Many recommend it not only in the summer, but throughout the year; while others are for strengthening alteratives, principally the pulsatilla rubra, with or without squill, and the different acids, during the winter; and the sea-water, and sea-bathing, or cold bathing, during the summer. As a continuance of two or three years from the commencement of the disease, with the

general observation, that they will engorge the circulation." Mr. White mentions, as the chief external causes, stagnation and pollution of sea-water. With respect to regimen, some recommended a milk and vegetable diet, others animal food and fermented liquors. But A. Cooper, in particular, who regards the disease as connected with constitutional debility, strongly recommends a nutritious diet of animal food, in preference to one of vegetation.—(Lancet, p. 74.)

Mr. White mentions, that the preceding plans of treatment are not, in general efficacious, except in some instances they may prove useful. "In early affections of the lymphatic glands (scrophulous glands), and from the want of a suitable and proper regimen, when children are delicate and scrophulous, a change of situation to the seaside, together with bathing, when they have acquired some strength, cannot be exceedingly proper; and in good general subjects, who have diseased lymphatics, those proper feeding, and most of necessary exercise, a journey to the seashore may be very useful, particularly if the salt water is drunk when, and in a sufficient quantity to become purgative. This, with the purity of the situation, which may frequently produce an increase of exercise, might answer every expectation; but these plans need cases that with a very little attention are easily cured."—(White on the Scrophulous, vol. 3, p. 104.)

They conclude in which Mr. White's remarks upon this part of the subject end is, that sea-bathing only deserves praise as a preservative, and as the only means of cure. He particularly confides cold-bathing for poor, weakly, debilitated children, whose little veins, enlarged livers, and impure bilious cough, necessarily indicate diseased viscera; such do not support these natural warmth, after cold-bathing, the lungs, and their consequent headache, cold tips, and pale countenances, are sufficient marks of its injuriousness.—(P. 207.)

Dr. Cullen entertained a very favourable opinion of cold-bathing, since he affirms that he had seen scrophulous diseases once benefited by it, after every other remedy.—(Ess. of the Nature of Phlegm, vol. 4.)

"Cold bathing, especially cold sea-bathing says Mr. Russell, is a remedy universally employed in scrophulous, and I believe with great advantage in many cases; for it not only appears to improve the patient's general health and strength, but likewise to promote the disengagement of enlarged glands, and the resolution of the disengorged vessels in the joints, when after they have attained a considerable size, and have continued for a great length of time. But in order that cold-bathing may be practised with safety and advantage, the constitution must have vigor to sustain the shock of immersion without inconvenience. If the immersion be successful by a general glow over the surface of the body, and the patient feels cheerful, and has a keen appetite, we may conclude that the cold bath agrees with him; but if he suffers on coming out of the water, continues chill, and becomes drowsy, we may be assured that the practice of cold-bathing does no good, and had better be omitted.

"In estimating the comparative merit of cold-bathing and warm-bathing in the cure of scrophulous complaints, my own experience, together with the result of different experiments on the subject with some of the most judicious practitioners of my acquaintance, would lead me to believe with more demonstration on the effects of warm-bathing. I should not even be inclined to discourage the practice in cases of scrophulous debility, even from observation, I am fully satisfied with regard to the beneficial effects of the warm bath to patients of phlegmatic constitutions, who were much affected with enlarged scrophulous glands. Several of these instances occurred in young women, about the period of life, who were in all respects healthy and vigorous, sharing the swellings of the glands and these symptoms of disease which were connected with fulness of blood.

"The essence of the warm bath is exceedingly grateful to most patients, and the practice is extremely safe. It may be employed at all seasons of the year, and in all weather, without danger or inconvenience, the risk of suffering from exposure to cold immediately after immersion in the warm bath, having been much exaggerated by prejudice. There is not even any good reason to believe in the expense of such a bath. The water itself, however, which is employed in warm

baths, are perfectly innocent; and, provided they do not become very excessively and uncommonly hot, which is the exception, but is guarded, as far as to remove the patient's mind from marasmus and pseudo-scurvy affections.

"If regular sitting waters, and sometimes spring waters, be resorted to, the late effects of warm-bathing in relieving scrophulous complaints; but as the practice is not attended with any inconvenience, but followed by any bad consequences, there can be no reason to be given the contrary till the trial be completely satisfactory; and I am convinced that the practice of taking bathing in cases of scrophulous will be more generally adopted after the knowledge of its beneficial effects are more widely diffused.—(See Russell's Treatise on Scrophulous.)

Nothing can be more satisfactory than Professor Thomson's tangible evidence which is so striking in the efficacy of the essence of soda, as it relates to scrophulous. In reading this, one may wonder how an effluvia so healthy should ever have fallen into neglect.—(P. 126.) In subsequent passages, however, the most gentlemanly evidence only a limited confidence in the means of relief. "Local sea-bathing, hot and cold waters, has often appeared to be of use in promoting the resolution of scrophulous swellings. The suspension of the bath must always be varied according to circumstances, according to the season of the year, the strength and habits of the patient, and the progress of the cure which the bath seems to produce. It is at all times difficult to distinguish between the scrophulous history arising from the scrophulousness of the system, and those which arise from the increased warmth of temperature in the bathing season of the year; from the exercise which patients going to sea-bathing necessarily take in the open air; from the change of situation and countenance; and, leaving the point stated, that the more resolutely diet and abstemiousness in what they are actually perspired to induce, as in their residing at sea-bathing quarters. It is not impossible, that those living on the seacoast, who become affected with scrophulous swellings, be thereby cured, derive equal benefit by going down the seacoast to reside in a place the situation of the country.—(See Thomson's Lectures, &c. p. 203, 204.) A still later writer declares he believed, that cold sea-bathing has a specific power over the disease.—(Lancet, Scrophulous, &c.) Yet the same surgeon is sensible of practical truth, will we can whether any plan has a specific power, or not, we can complain. If that disorder is sometimes relieved by it. And that this is the fact is admitted by Mr. Lloyd, when he says, "cold sea-bathing, however, is certainly useful, when judiciously applied."—(P. 41.)

With regard to decoction, Mr. White remarks, indeed, when done length of time the enlarged glands have acquired a degree of hardness and immobility.

Mr. White, after explaining stricture in the stomach, and diet, as preventive of a stricture as well as a preservative of the disease, proceeds to explain his own practice. The first external symptoms, such as swelling of the lips, side of the face, and of glands upon the chin and round the neck; also other symptoms usually denoted as stricture, viz. hardness of the skin, eruptions on the back of the head and different parts of the body, redness and swelling of the eyes and ears, are accompanied, according to Mr. White's conception, with an inflammatory distension, though without such as to require bleeding. Called with the medicines which this gentleman recommends in the treatment of the foregoing complaint. It is not safe given to such quantities as to render it a specific cure, either by the intention to cure it, but in small doses to soothe. Thus says Mr. White, "It is usually larger in the intestinal tract, a great quantity is taken into the milk, and the patient is susceptible of cold than what makes in the disease. The first and perhaps the second dose may prove purgative, which is in general necessary effect; but afterwards, the same quantity will induce no more; it is sufficient to keep the body open; and should be of service for that purpose. I have stricture with it, and it is usually purgative, even after it has been treated, according to the common practice. If this could be a preceding medicine, a few grains of the oil with it, or even of some mucous powder, may be added to the medicine. By this simple method, however, Mr. White, that of the symptoms before mentioned will, in a short time, disappear; but if the patient

World contains land, and retain their space without striding innumerable miles, as many divers have been from external applications, particularly the steam of warm water. I have used a variety of medicinal baths from nature, but am inclined to believe that the advantage was particularly derived from warm water. At other times, I have directed the patient to lie with electricity, stimulating the pulsat, and drawing sparks from the tumor, with a slight figure of inflame the tumor was united. After the application of the steam, or the use of the electrical vesicator, I have sometimes rubbed a tube of the ammoniacal volatile oil, the balsam and neighbouring parts, in applied the ammoniacal applications or ammoniacal cream, water, or oil to the system, as a stimulant and evacuant, of course, and by osmosis. Dr. Ware adds, that in such cases, if the tumors should suppurate and burst, the parts will, in most instances, heal without much trouble. For eruptions on the head, he recommends applying the wet return, alum, camphor, or the Great Oil, once every second day. For the roughness of the skin, which is generally followed by eruptions, he also advises the ammoniacal vesicator (see last article), calomel, solution of sal tartar, or of the hydropic acid, as outward applications. "That last says Mr. White will seldom fail to check the progress of the complaint, and, dry the sores; and, in the quantity of half a pint of warm water, the use of a full seton is productive of any pain. If the eruption should increase, and require any unguent application to prevent the adhesion of the flaps, the ointment below mentioned may be applied; the best remedy will be warm bathing, and, when practicable, the hot-water bath a preference."—(P. 114.) The author next mentions his having occasionally recommended the virtues of emollient, tumour extract, from yam, hyacinth, domestic species, or cornelian; and that he sometimes found advantage derived from attractant drives. We need not doubt this professor's mode of treating affections of the eyelids, as he is a native of Switzerland, whence the eye and eyelids are the articles of business and of knowledge.

For the sake of individuals in the laundry, remaining safe, sanitary, abstemious, Mr. White speaks very highly of the effects of the steam of warm water; and cautions his agents unhesitatingly employing calico which will often affect the sensitive little, but the child readily. Mr. White assumes his sweeping is made on machines large enough to hold a gun and a half or two pairs of boiling water. From the top proceeded a narrow pipe, ten to twelve inches long, through which the steam passed. Near its end, which was flexible and curved, was a point for the greater convenience of directing the steam to the desired parts. The water was easily kept boiling by means of a lamp under the machine. Mr. White says that the agents should be employed twice or three a day, and a piece of flannel or cloth afterward applied. The body should also be kept open. In climatic unhealthful areas, mercurial preparations, according to Mr. White, need likewise to be given, and if they affect the child much, inoculation should be suspended.—(P. 117, 118.) For extreme eruptions of the face, resorted to be antiseptics, I would very particularly recommend a trial of calico, which should be used both externally and internally.—*Free Inquirer.*

When the glands of the neck or other parts of the body tend, to a state of suppuration, it is very slowly, the skin appearing gradually this and of a deep red color, and the tumor swelling forward. In situations, Mr. W. never recommends the use of the lancet or caustic, for an artificial opening is made, it will be a long time before the skin gives way; and when it does, the opening will not only be very small, but often unfavorable in its situation. Mr. W. adds, that the contents will often be found to contain more pus, or like a salivary of body; and the pus keeps well contained for a great length of time if no opening is applied. He found a solution of pure hyposulphite of soda when used more freely, and the constant application, or some similar outward application, the best method of treating the disease.

We need not describe Mr. White's powder in the minutest of scientific particulars, as the subject is fully considered in the article before us. It appears, however, that he confirms the efficacy of silicate of soda in whitening and preserving white surfaces, when the surfaces are

loss are affected with stream-of-consciousness—(F, ID). What may be done in these cases by the patient and mental use of idiosyncrasy, remains to be proved by further experience; and it is certainly a prediction, the power of which is probably outside the patient's imagination.

Wheaton improves the practice of Mr. White in administering calomel, occasional purgatives, the different laxatives, emetics, &c., with the slow pill, cathartics, and laxative treatment of the present day, but persists in very material differences between them, especially when the struma is such Mr. White takes upon attention is diet, clothing, &c., is taken into the account. Mr. Lloyd, who has obtained Mr. Alcock's promise is confident, says it does not in his opinion that "the disease is only to be cured by removing all sources of irritation, and restoring the natural and healthy functions of the digestive organs."—(P. 45.) By means of leeches, Mr. Lloyd removes existing spasm; the active is therefore removed, so far as it can be followed, in such cases as are locally known. The restoration of the functions of the digestive system is also a thing worth aiming at; and the only difference of my views from those of Mr. Lloyd is that I look upon the disorder of the digestive organs to be in general only a complication or effect of the system, such as, ulcer, abscess, diseased joint, &c., and not the causing cause; the treatment, when beneficial, depends on our on the principle of improving the general health, by the removal or diminution of one of the most fatal consequences of the original disease. It is hardly necessary to inform the profession that the treatment described by Mr. Lloyd, in addition to the usual advice about diet, clothing, and avoidance of damp and cold, and the utility of good air, exercise, &c., consists in giving the patient five grains of the gel. hyal. every eight or half a pint of sweetened, orange, &c. triacate. And it is a certain loss of the day, were he bent on mercurial measures as had to opening medicines. This plan is powerful if the humors become copious; and then, with a view of preventing a relapse of the humors into their former state, Mr. Lloyd continues the exhibition of alterative doses of mercury in an moderate time, the pills now being given to the powdered calomel pill, is doses of five grains three or four times a day. In this practice is exactly like that of Mr. White, viz. small doses of calomel with purgatives. When acidity prevails in the stomach, small doses of soda air is recommended; and when the stomach is weak, with loss of appetite, chills, shivering, and calidness of the body. A further, with pepper and wine, is disapproved of, as already stated, not as a counter to be placed in one bottle.—(Lect. on Scrophula, a. 26.)

[illegible]

conceitly proposed the marriage of these; but its effect is very God-fail, and inconsiderable. "Professor Emerson says Mr. Russell had fringed me with the string observations with collected apoplexy in 1855. I employed marriage of him in various cases of vertigo, without having derived benefit from it; in a single instance. These patients, indeed, he admits, not well his leader a source of surprise of these; but then he led an opinion to accept the case in the effect of the vertigo. In order to do this, the contrary, the disease has produced severe sickness and depression in himself, and the patients got daily worse. In the state of him was required, and only a few days employed. The relief experienced from the vertigo, on of the marriage of him, led to a double with regard to the marriage effects which the use of it had pro-

wood, with sulphur and calomel, or the subcarbonate of soda, with rhubarb and calomel. — (*Lancet*, vol. 4, p. 34.)

As beyond the highest merit, the sulphate of quinine, and the preparations of iodine, should also be recommended.

The local treatment preferred by Mr. White has been already described. I have only a few words to add concerning this part of the subject. Dr. Colles states, that, in his practice, he had very little success in discussing scrofulous tumours by topical applications; and that a solution of the succatum saturni, though sometimes useful, was frequently failed. Dr. Colles found the aqua ammoniac not so more successful. "Fluorides of silver and lime have been frequently found to be fatal; and poisons seem only to bring on a suppuration. I am doubtful, if this last be ever procured with advantage for scrofulous tumours, supposing judiciously to suppose, but never after any degree of inflammation has come upon them; and, therefore, poisons, which constantly induce inflammation, prevent that absorption of tumours which might otherwise have happened." These views scrofulous tumours have advanced towards suppuration, Dr. Colles thought, that inserting the aqueous opening, or making one with a lance, was useful.

With respect to ulcers, Dr. Colles remarks, that antiseptic preparations of either mercury or copper, have been sometimes useful in bringing on a proper suppuration and thereby disposing the ulcers to heal; but they have seldom succeeded, and, more commonly, they have caused the ulcer to spread more. The mechanism from which Colles says heat began to rise, was first, skin mixed with some mild ointment. But this conducted matter gives the weakness in keeping the sores continually covered with linen wet with cold water in the daytime, and some ointment at night. He usually found an order too irritating, and its removal sooner better than constant water. — (*First Lines of the Practice of Physic*, vol. 4.)

Formerly, the corruption of scrofulous ulcers was unfixed; but this method is now considered as being, for the most part, ineffectual and unnecessary, with the exception of diseased joints, and a few other parts, which frequently require being amputated, for the sake of saving the patient's life. Certainly no particular drugs (generally speaking) would almost calling out scrofulous glands and tumours; the objections to the plan are founded on the pain of the operation; on the number of such glands frequently existing; on their often subsiding, either spontaneously or by surgical treatment; on the operation doing no good in the general affection of the system, &c. When, however, a scrofulous testicle, bone, or joint, seriously impairs the health, and endangers life, the very existence of the patient demands the immediate removal of the diseased part. Wiseman states, that he was in the habit of letting out scrofulous glands and tumours with great success; but, for reasons already offered, most of the moderns begin with operation in general unadvisedly.

Caustics have been employed for the same purpose instead of the knife; but as they effect the object as slow as certainly, more painfully and seriously, and cause extensive ulcers, they are disused by all the best surgeons of the present day.

Some authors have advised eating liver, and keeping their faces in order to prevent any ill effects from the breathing of scrofulous air. There are certainly quite unnecessary for any purpose of this kind; but they are extremely useful as a part of the local treatment of scrofulous joints and ulcers, as we have seen, particularly mentioned in the articles *Joint*, *Liver*, *Ulcers*, and *Wounds*.

Mr. Bristle states, that leeches have hitherto been chiefly used in diseases of the bones and joints; but he adds, that it is reasonable to suppose, that they might likewise be useful in the cure of enlargements of the glands and other scrofulous tumours, if inserted in the most judiciously of the part. The only objection to their use is the fear which they have, and which, in certain situations, one would particularly wish to avoid. When the tumour is thickly covered with the integuments, the leech may be made directly over it, and kept open with the above ointment. In other cases, a small pea size or more, may be in-

serted by the side of the tumour. This method would be objectionable for scrofulous glands in the neck, in consequence of the risk, but it might be employed when the tumour is situated. — (*Illustrations on the Scrofulous*, vol. 2.) The late Mr. Croxall used to apply blisters to scrofulous swellings, and maintain a discharge from the part. And a more ready process is that of producing irritation of the integuments, by vesicating tumours and abscesses, by means of the tartar emetic ointment. — (*Illustrations on the Scrofulous*, p. 162, &c.) The good effects of iodine upon scrofulous tumours, kept as an internal medicine and local application, seem now to be exciting considerable attention. Dr. Smith has made writings of the medicine and breast, in particular, yield to this powerful medicine. — (*See Index*). The profession, however, are still in want of some decided and accurate reports upon the subject, which is at present obscured by the speculations always attending the first introduction of a medicine, supposed to have power over any disease that has been found so little under the control of physic in scrofula. I beg, at the same time, the attention of every surgeon to the strong recommendation with which iodine has been brought into notice, and to its great medicinal powers, as already verified by thousands. — (*See Illustrations and Index*.)

Preparation of lead, chalks dipped in cold water, and water, or weak vegetable acids: rubs; sea-salt mixed with life; the ammoniac liniment; a mixture of ether and the trinitrate system; and leech positions; from a long list of applications, which have been employed for scrofulous tumours.

According to Mr. Burns, moderate pressure, by means of adhesive plaster, wrapped with one application of cold water, is one of the best plans of treating scrofulous ulcers, when their situation admits of it. In other cases, he recommends applying a powder, for years of which causes of various sorts, and the salt of tartar alone. A piece of dry flax is used to be applied, and a compress, wet, with a mixture of castor oil and water, is used occasionally to keep the compress in cold water.

The use, most in a good constant dressing, when it is needed, is in scrofulous sores with the progress of the ulcer. The mag. hydragr. nitric rub, and strong hydragr. nitric, are the best stimulating dressings. Positions of bread and sea-water; solutions of alum, solutions of copper, and the hydragr. nitric, solutions of the nitrate of copper, arsenic, and silver; the rectified spirit of the wood-spirit distilled; flat dipped in lemon juice, or vinegar and water; a mixture of ammoniac and cerium, superin. (Scott on Chronic Inflammation, &c.) are among the applications to scrofulous ulcers.

For treatable sores, diluted hydrophosphate of arsenic, containing containing opium; cerum and liniment positions; a solution of opium; and carbonic acid gas, are sometimes recommended.

The following are Mr. Russell's sentiments respecting the treatment of scrofulous sores: "Scrofulous conditions in general do not agree well with stimulant applications. In the treatment of scrofulous ulcers, under the ordinary circumstances of magnitude, the simplest and mildest dressing answers best. When the patients are using a course of sea-bathing, it is usual to wash the sores with sea-water, and above the necessary application of the sea-water being the treatment of the whole body. Cold spring water is likewise a favourite application with many practitioners; and from much observation, it appears that the application of cold is well suited to counteract the state of inflammation which accompanies scrofulous sores. Preparations of lead are, upon the whole, very convenient and useful applications, provided the solution be used in a state of sufficient dilution to prevent irritation. Liquid applications are applied by means of wet flax, which is covered whenever it dries, so that the surface of the sore may be kept constantly moist, when under treatment of treatment. Upon the same principle, simple ointment and Royle's cerum furnish the best dressing in ordinary cases.

Scrofulous eruptions of a solid nature, in the more external parts of the body, are little adapted to the practice of local dressing, unless they be attended with symptoms of inflammation, but as soon as they

elderly laboring with regard to the cause of the complaint, which has been referred to the irritation of sea, and this alone, in a supposed peculiar condition of constitution, not defined, not taken at all seriously.

Mr. Pott, as we find, describes the disease as always beginning at the lower part of the scrota, but there are exceptions. Mr. James Esdaile has recorded an instance of its origin from the root of a gland, which had been employed in displacing root for the destruction of a stump, and some cases are said to have taken place in the foot.—(*Ed. Earle on Med. Chir. Trans.* vol. 12, p. 255.) One circumstance is noticed by the latter writer, which, if it prove generally correct, naturally influences the prognosis and treatment. He says, "the inguinal glands are often enlarged, but they will generally subside on the removal of the diseased scrotum; thereby proving that this disease is not excessively communicated in the nature of the abscesses."—(*Id.* p. 255) He seems only one exception in this statement; a case where a testis, lamed, suppurated, and increased the size of the scrotum as the primary affection in the system.

If there be any chance of putting a stop to, or preventing this mischief, says Mr. Pott, it must be by the immediate removal of the part affected; namely, that part of the scrotum where the sore is; for if it is suffered to remain until the testis is affected, it is generally too late even for castration. "I have many times made the experiment; but though the scrotum, after such operation, here in some instances healed kindly, and the patients have gained from the hospital seemingly well, yet in the space of a few months, it has generally improved, that they have returned either with the same disease in the other testis, or in the glands of the penis, or with such was complicated, with pale tender countenances, such a total loss of strength and such frequent and severe internal pains, as have ultimately proved a diminished state of some of the vessels, and which have some been followed by a painful death."—(*Id.*)

Mr. Esdaile's experience has taught him, that no topical applications, nor internal medicines have the slightest influence over the disease. The scrotum, he says, is the only resource, and it may be supported with confidence provided the whole of the diseased mass can be removed. Even when the inguinal glands are enlarged, he advocates the same practice. Also, when the testis is affected, provided the spermatic cord is sound, he advocates, that it is right to give the patient the chance of recovering; and when considering the desperate results of Mr. Pott's operations in this case of the disease, he has seen the almost successful cases, is which no relapse had happened several years after.—(*See Pott's Works*, vol. 3, ed. by Esdaile. Also, *Mr. Esdaile's Essay on Ecthyma*, to which are added the *Chancery* and *Cancer*, &c. *Medicines*, 1852. *Ed. Esdaile on Chancery Cancer*, in *Med. Chir. Trans.* vol. 12, p. 256, &c.)

SCROTUM, *Sarcinoma* Thickening and Induration. The improvement of Esdaile's local treatment is better, than cases of enormous growth of the scrotum are extended to women, scrotum, as, at least, that they are released, directed to cold cauterization, since most of the scrotum which have been seen in Europe, except from Asia and Africa. The scrotal tumor of Desfontaines, formerly considered of external solution, says Esdaile, is perhaps the only well authenticated instance of the growth of such a disease in our own climate; and it is so, much smaller than the instances related in the *Epithymides* German, for the year 1802, in the scrotal writings of Desfontaines, and the scrotal tumor of Desfontaines, and those which Esdaile has treated in most men in Egypt. The scrotum of Esdaile, after they had reached their full size, weighed more than 25 kilograms (between 50 and 75 pounds).

Several cases of this enormous disease are recorded by other writers, particularly by Dr. Cullen, Dr. Tully, and the celebrated Desfontaines. Esdaile says, in Mr. Desfontaines's specimen, a considerable fleshy substance, which was a portion of diseased scrotum.

In the case which Esdaile had an opportunity of seeing in Egypt, the scrotum was, and when the operation was executed, was laid below, and exposed from the sides by a sort of pedicle. "Esdaile (on Esdaile's scrotum), the scrotum presents a pedicle of fat, from which is projected by particular lines, containing, which the scrotum is a part of the scrotum, and

respond. Upon a large portion of its surface, especially when the case is of long standing, yellowish scaly crusts and always seen, the detachment of which immediately leaves to many small fungous ulcers, emitting an offensive discharge. The tumor is soft and fluid at some points, but solid at others. It may be handled and pushed in different directions, without the least pain. The patient is only annoyed by its weight, and the impediment which it causes to his walking walk. Hence, he is recommended to employ a suspensory bandage. In consequence of the situation of the scrotum, the urine discharges over the swelling, but without causing any irritation. In most of the cases, such by Esdaile, the spermatic cord and testicles were in the natural state, situated at the sides and at the root of the swelling. The spermatic vessels, however, were somewhat enlarged and dilated. All the patients were likewise more or less affected with elephantiasis.

Esdaile, Esdaile attempts to explain the cause of the complaint in Egypt, but, we think, without any degree of success. As the affection is seldom seen in cold countries, climate has probably a chief effect. Esdaile remarks, which long becomes a good deal in a strong position; the scrotum, however, were in the Egyptian, and the consequently perishing state of the scrotum, the cause of the tumor, and particularly their situation, on the part, a necessary consequence of syphilis in that country; had perhaps, almost of every; and the moderate use of the warm bath; and the moderate use, which will not bear the heat of removing.

The enormous magnitude which this scrotum disease may attain is almost incredible. The case recorded in the *Epithymides* German, weighed about a hundred kilograms, or more than two hundred weight. Another, described by Esdaile, was calculated to weigh about one hundred and twenty pounds; and this scrotum, however, was in Egypt, but of more moderate size, nearly as large, and all of the same character.

A very curious example, in which a similar disease affected the labia pudendi to a surprising degree, is also detailed by Esdaile. The woman was a native of Cairo. In the early stage of the disorder, we may be permitted to suppose, confirmed with scaly crusts, ulcers, and excoriated with scaly crusts, before reaching the stage, and, or the excitement of mercury, the scaly crusts, of the scrotum of elephantiasis. These scrotum, as we are assured by a scrotal, scrotal, scrotal, scrotal, and the application of caustic, passed of scrotum, and Esdaile very properly continues with experiment.

When the disease reaches every stage that is to be feared, and the scrotum reaches the patient's life, it is a case of death, scrotum, the operation of the scrotum with a knife becomes proper. In this proceeding, the chief skill consists in doing so lightly to the spermatic cord and testicles, which are generally perfectly sound. As the scrotum of the scrotum is not furnished with large vessels, the hemorrhage need not be feared. Care must also be taken not to wound the corpora cavernosa penis, and the urethra. After the operation, the skin is to be brought over the diseased scrotum as much as possible, with adhesive power and a bandage.

Mr. Desfontaines successfully removed the diseased mass in the scrotum of the French market Desfontaines, and Esdaile performed the same operation with success when he was in Egypt. Dr. Tully, of the scrotum of the Christian, who returned with a tumor, which weighed seventy pounds, and the patient, who was a negro, and also affected with elephantiasis, severely recovered.—(*See Esdaile's Works*, vol. 3, p. 25, &c.)

It is probable that some of the cases which occur in warm countries, are analogous to the elephantiasis; but I do not believe that the scaly crusts which are represented by Esdaile as occurring in the cases which he saw in Egypt, have been shown to exist in the instances which have been given in cold countries. Now, indeed, did they take place in the scrotum recorded by Dr. Tully, the scrotum of the patient having been in the scrotum.—(*Esdaile's Works*, vol. 3, p. 25, &c.)

ESDAILE. The operation of removing a scrotal tumor, through the scrotum, into the bladder, for the purpose of amputation, is known to the patient for a while to see.—(*See Esdaile's*)

smaller than they really are. This is the only case in which stimuli of being treated as a distance. The eye, however, producing the disorder is usually acted on by individual causes, and certain occupations, and such conditions as impede the nerves. A supposition of perception is alleged to be sometimes a cause.—(*Archiv. f. Ophthol. der Wissenschaft.* i. 2, p. 265.)

A sound eye likewise does not always judge with accuracy and consistency of the magnitude of objects. This may arise from three causes. In order to judge rightly of the size of any thing, its position, distance, must be known; for the more remote it is, the smaller will it seem to the eye. Hence, any misapprehension respecting the magnitude of an object, is constantly connected, unless the distance be ascertained. This is invariably something relative. A single large object, surrounded by many smaller ones, always appears to be larger than it really is; as this vessel, an object whose magnitude is known seems smaller than it actually is, when one has been a little previously looking at numbers that it still larger. Lastly, the refraction of the rays of light in the eye, by which objects as they are made to appear large or small, is also always accompanied in the same degree, as the eye seems to find things equally felt and distanced with its lens. Hence, if one sees the same object well appear in the same eye, and at the same distance, larger; or smaller than usual. Sometimes, however, the eye judges as to the size of the magnitude of objects, and there is power by regarding the case as an infirmity or disease. It is for the most part owing to a defective sensibility in the nerves, caused by some disease of little or nothing upon the eye, and is generally seated in the optic system. A man is seldom easily thing seemed too small; and never than a really was, was cured by means of an emetic, bark, an opium, and opium.—(*Lehrb. der Augen.*)

Sometimes to the eye, under circumstances of disease, straight lines appear serpentine; perpendicular objects straight; things standing upright, to be inclined, &c. The son of a distinguished artist began when seven years old to learn drawing under his father, who was much surprised to find all the objects which the young pupil represented drawn upside down. It was at first supposed, that the child might be practicing the reverse of objects in joke; but he affirmed that the things were drawn exactly as they appeared to him, and there was no manner to doubt his word. When ever an object was turned before he took a sketch of it, he represented it in the natural position, showing that the irregularity occurred by the eye corresponded perfectly with the inversion formed on the retina. This state of vision existed at the end of a year.—(*See Journ. Med. Arch. der Naturg.* 1861, Feb. 1862.) All the preceding cases are not done by Richter as depending upon a sensory peculiarity of the nerves, occasioned by the effect of some stimulus. The irritation, he says, may be of any kind; but experience proves that it is mostly seated in the optic system. These defects of sight may generally be cured by first eliminating causes and purgatives, and afterwards, having recourse to remedies for strengthening the nervous—bark, alcohol, iron, male, vitamin, issues, &c. One mark of a very weak and imbecile eye is, when objects after being looked at a good while, and presenting a right appearance, begin to swim, drift about, mix together, and at length become quite unrecognizable. This peculiarity happens when the objects retained are small and strongly dissimilar. Here some remedies, both general and local, to have the effect of invigorating the nerves are required. However, sometimes the infirmity is partly owing to the operation of some species of irritation, which will require removal, as the tonic remedies and applications can avail. Indeed, in particular cases, the disposition of such irritation is alone sufficient to accomplish the cure.

Sometimes all objects appear to the eye as if they were in a more or less dense mist. This defect is visible to almost every eye either in some slight capacity of one of the features of the eye, or to excessive debility of the optic nerves.—(*See Richter, Archiv. der Wissenschaft.* i. 2, p. 333, &c.)

SINUS. A long, narrow, hollow track, leading from some sheath, directed bone, &c.

SOUND. An instrument which surgeons introduce through the nostrils into the bladder, in order to determine whether there is a stone in the vesica or not.

The sound is made of highly polished steel, that it may be used most effectively covering up to the surgeon's finger the assistance of any thing against which he can say strike. It is also generally rather less curved than a catheter, so that its curvature may be more easily introduced to the lower part of the bladder, where the stone is most frequently situated.

SOUNDING. The operation of introducing the sounding instrument.

Sounds are generally introduced much in the same way as catheters, either with the curvature towards the side of the vesica; or the curvature towards the side of the urethra; in which last method it is necessary, as soon as the head of the sound has arrived in the prostatic urethra, to bring the handle of the instrument downwards by a semicircular movement to the right, while the other end is kept as much fixed as possible. This is what the French term the *curve* or *tour de sonde*; a plan that is often followed at the present day, though, except in very suppurated subjects, it has no particular recommendation.

When a patient is to be sounded, he is usually put in a posture very similar to that adopted in the lateral operation. For the stone, with the exception that he is not fixed in this position, as there is sometimes an advantage in making the patient stand up, in order that the stone may come in contact with the end of the sound. The instrument, having been introduced, its extremity is to be moved and moved in every direction, until it there be a catheter, the pressure will usually be indicated by the motion against the back of the sound.

Surgeons have sometimes both fixed in the bladder after death, although they could never be discovered with a sound while the patient was alive, suffering all the symptoms of the calculus. The celebrated French surgeon, M. Pons, has also circumvented, as he was so fully convinced of there being a stone in the bladder, sometimes rather to his regret, as he has been told, not to use a sound, that, on the contrary, he gave directions for ascertaining the fact. Hence, while the sound symptoms of a stone in the bladder continue, patients should be sounded several times before a positive opinion is delivered respecting the nature of the disease. When, during the operation of sounding, as the stone has escaped from the bladder, the inner surface of the vesica comes into contact with the end of the sound, and such a sensation may be communicated to the surgeon's finger as leads him to suspect that a fungus, or some other singularly sensitive substance is contained in the bladder. In such cases patients have actually been cut for the stone, when no foreign body whatever was present.—(*See Richter, Archiv. der Naturg.* i. 2, p. 271, 272, &c. 2. *See Zinkow.*)

SPECULUM. An instrument to facilitate the examination of parts, and also the performance of operations on them: thus we have speculum, nasal, anal, &c.

SPIRACULUM. (From *spirare*, to destroy.) Synonymously, by this word, complete incision, which is usually preceded by a stage of the disorder, termed gangrene. *See Rheumatism.*

SPICA. (From *spica*, an ear of corn.) A name given to a kind of fissure, is consequence of its form being thought to resemble the ears of an ear of corn.

In order to apply the spica bandage to the shoulder, the margins of the assile tract, that is protected from the effects of the pressure, by means of soft compresses, and covered of a common roller as then to be placed under the armpit, in the axilla itself. After conveying the bandage backwards, obliquely over the scapula, the surgeon is to bring it forwards over the injured shoulder. The roller is then to descend under the armpit, then to be carried upwards again, and made to cross at the distal vessels. It is now to be carried obliquely over the front of the chest, and under the axilla a second time, where the end of it is to be placed or stitched. The bandage is next to pass across the back, over the part of the roller previously applied in this situation, and is to be conveyed round the head of the scapula, so as to form a *tricus* or *delta* with the first circle of the roller. There are four *deltoidei* or *tricus*, each of which covers about one-third of the preceding row, are to be made, and then the upper part of the arm is to be care surrounded with a plain circle of the bandage. This last circular application forms between it and the cross previously made a triangular equilateral space, technically named by writers *gros*

with sticking power, and, if possible, limit. Another accumulator is likely to be provided, if practically warranted, and logical applications. Mr. Dixon lately actually made the experience of a positive air connection between, in water, indeed, the water had previously had liquid nitrogen. The pressure was repeated every third day for six weeks, during which time the child's health continued unstable. The wounds were gradually healed, but the places having been rubbed off one of the punctures, the gas often met the opening could not be healed, the discharge, first having been of an aqueous nature, became purulent, and soon escharic. This case was also attributable for the ill of the method, as the large amount covering the stanzas were flamed, and had no disposition to contract.

The married pair, assisted by Sir Aubrey Cooper, will serve to show the benefit which may be derived from training.

Johns Appleton, Baltimore, Md.—My son, now born on the 19th of May, 1867, and his mother, immediately after his birth, observed a tumor, and inflammation, on the back, of the size of a large walnut. On the 22d of June, 1867, the child was brought to my house, and I found that, notwithstanding the inflammation, the head was not excessively large; and the eruption of the legs were pointed; and the limbs and trunks were discolored extensively. I applied a cataplasm around the child's waist, so as to compress the tumor, being directed so to do so from considering it a species of hernia; and that the deficiency of the spine might be compensated for by external pressure. The pressure made by the tumor, had no unpleasant influence on its pulsatory power; it actually and twice continued to be properly discharged, but the mother feared that the child was excessively convulsed. At the end of a week, a piece of plaster of Paris somewhat thickened, and that below, partly fixed with a piece of horse hair, was placed upon the surface of the tumor; a mass of adhesive plaster was applied to prevent its falling to the ground; and a roller was roundly secured the waist to bind the plaster of Paris firmly upon the back, and to compress the tumor so much as the child could bear. This treatment was renewed until the month of October, during which time the tumor was enlarged about three times a week, and the mother reported that the child was occasionally convulsed. When the child was five months old a brace was applied, and it is seen to that which I sometimes use for scapular hernia in children, and this has been continued ever since. At the age of fifteen months, I began to make use of my splint; it could travel almost freely and support a pair of pants. At eighteen months, by some accident, the trunk slipped from the splint, which had become of the size of a small hoop, and the mother observed, when it was restored that the child appeared in some degree ill; and this was always the case, if the brace was left off for a few minutes, and then re-applied. At fifteen months, he began to walk, and at that time of age, he could walk alone. He never grew to crawl, run, jump, and play, except in other children. His position of mind did not appear to differ from those of other children. His memory is retentive, and he learns with facility. He has the vowels and small part of the first year, and the beginning of the second year. His head previously and subsequently to the tumor closing, has possessed a disposition to come partly of the body. The tumor is kept by the brace entirely within the clasp of the splint; but when the brace is removed, it comes because of the size of half a small orange. It is therefore necessary that the use of the brace should be continued. When the brace is removed, the tumor can be readily passed through the frame over the clasp of the splint. —*Med. Chir. Trans.*, vol. 2, p. 251, &c.

The story was also published by The Audley Cooper, and points that since Britain may sometimes be treated in another place, so as to avoid a permanent one.

[illegible]

finding that if the whole was treated, the process would be far great upon the lesion. I thought it a fair opportunity of course was taken by the effect of treating the swelling by means of a very fine pointed instrument, and by subsequent process to bring it into the state of the sperm habit in America's child. I therefore immediately provided the father with a strychnine, and made it about two ounces of water. On the 10th of January, finding the disease no longer to move it had been pronounced, I opened it again, and in the same manner, and discharged about four ounces of pus. The next day when the fluid was to be treated, on the 15th it was found that it had become more fluid, and I opened it again. On January 22nd, the disease was as large as at first; I opened it again, and discharged the fluid. A strychnine was applied over the incision and around the abscess. February 1st, it was again opened, and three ounces of fluid discharged. On the 15th, three ounces of fluid were discharged. On the 18th, the same quantity of fluid was evacuated as on the 15th; but instead of its being perfectly clear as at first, it was now opaque, and it had been gradually becoming so in the three former operations. On the 20th, the same quantity of fluid was taken away; it formed a layer was found over the incision and around the abscess; a piece of gauze was placed upon the fluid rather over the incision, and another piece over the puncture to make it. On the 21st, three ounces of fluid, of a more liquid kind, were discharged; the strychnine was again applied. On the 22nd, the same quantity of fluid was taken away; the fluid was now more opaque, and the child suffering considerable constitutional irritation, was ordered calomel and ipecacuanha, and the rules were discontinued. On the 23rd, the disease was not more than a quarter of its former size; it did not swell; the integuments were thickened, and it had all the appearance of having undergone the adhesive inflammation. On the 26th, it was all well reduced in size, and felt solid. March 3rd, the swelling was very much lessened; the skin over it thickened and granulated; a crust was again laid over it; a crust was put over the incision, and a second strychnine was applied. March 12th, the disease was much reduced, the skin covering it was a little enlarged. On the 15th, it was that was still a little enlarged. On the 27th, the effused considerable lymph was considerably reduced in quantity, and of a very fine texture. On the 28th of May, nothing more than a little protrusion of skin remained, and the child appearing to be perfectly well, the bandage was removed. On the 10th of the 29th, the child was attacked with the measles, and went well through the disease. The skin now large facial from the base of the neck; the centre is darker in the middle which is marked, and the appearance of a wart is produced in its tendency towards the skin. The pucker of the neck is very obvious, leaving slight indentations. (See *J. Med. Chir. Trans.* vol. x, p. 287-289.)

At the time when Sir A. Cooper presented this case to the Medical and Chirurgical Society, it had been under his observation two years and a half.

The first of the preceding observations emphasizes the patients' treatment adopted by the larger pediatric, and consisting of the application of pressure to the halves of a brass jaw-joint. The second refers to such cases of cure by maintaining the swelling from time to time with a needle, and exciting the subjects' tuberculosis, which, with the assistance of nature, stops the disease altogether. That is to say, in such cases no direct cure.

The infant is usually born with transient erythema of the face, but covered on the head. There is a swelling of the skin on some part of the skull, and through the opening a sac, composed of the dura mater, protrudes, covered only by the integument. The face is heavily marked with such a swelling situated over the vertex of a fetal lobule. The face is intensely anemic, small, pinched, with prominent nose, dilated eyes, the child, holding up the protruding and applying pressure, was tried, and followed up for some time, without the occurrence of any noticeable symptoms. The pinched face was somewhat made worse by the mother's anxiety; yet the child suffered no harm from the swelling, and some general convulsions occurred. At birth, however, sensation of the swelling then alone, was still more increased, and readily such.—(See *Med. Clin. Trans.* vol. 7, p. 427.) *General Remarks*

wild at one, they ought, says Boyer, to extend to white length. "For instance (says he), the simple hairs of the thighs of very young children, are painted spots which I suppose, arise from the upper part of the thigh, to the lower part of the leg. Generally speaking, the longer spots are, the better they fit the limb, and keep the features steady."—(Boyer, *Treatise on Med. Chir.* c. 3, p. 30.)

The tendency of epistaxis depends upon its breadth and the thickness of the flesh. For the former two are sufficient, for the upper and lower lips are often torn; and for the latter two, the nostrils are often torn.

In cases of fractured thighs, when the straight position is preferred, the external splint should extend from the crista of the femur to above the distance between the middle of the foot, while the lateral one should reach from the upper and internal part of the thigh also beyond the sole of the foot. With respect to the lateral splint, it is indifferent whether it only reaches from the crista to the knee, or even to the lower part of the leg.

The lateral splint for a broken leg ought to be sufficiently long to embrace the knee and contain the tendons of the foot and ankle. When the straight position is adopted, a splint is frequently laid more the front of the leg, than the points in the lower part of the limb. Now, however, can ever be applied under the limb, as three the latter itself never permanently affords the necessary degree of support.

Of all the different pieces of the apparatus for the treatment of fractures, the splints are by far the most important and essential. Without them, indeed, it would be in vain to attempt to keep the extremities of the fracture from being displaced.

Splints are generally composed of hard materials, the soft parts of which pressure upon the skin must always be counteracted by placing a sufficient quantity of cotton, wool, cambric, flannel, between them and the limb.

In order to understand, however, the position which should be made the support in the elbow and application of splints, many remarks offered as the article Fractures must be consulted.

SPONGIA PLAZARATA. (*Prepared Sponge.*) *Sponge* (true). Prepared by dipping pieces of sponge in hot sulphuric acid, and squeezing, and pressing them between two iron plates. As soon as cold, the substance thus formed may be cut into pieces of any shape. It was formerly much used in dissecting animal organs, for which it was well adapted, as when the work ended, the elasticity of the sponge made it expand and closed the opening. However, the best modern surgeons seldom employ it.

SPONGIA LINTA. (*Woolly Sponge.*) This medicine, which the preparations of wool are so likely to improve, was often given in the form of lint, as in cases of hemorrhoids, in which particular instances much efficacy was imparted to allowing the lint to adhere gradually under the ligament. Lint-sponge has also been exhibited in many venereal diseases, and in chronic inflammations of the prostate gland. The dose is from a scruple to a drachm.

STAFF. An instrument of considerable importance in the operation of lithotomy, being in fact the key to the prostate or knife. It is made of steel, and its handle is generally rough, in order that it may be more securely held. As it is intended to be introduced through the urethra, its shape ought to be principally determined by the natural course of that passage. The English generally employ a staff, the curvature of which forms the segment of a larger circle than that described by the curvature of a staff used by the French practitioners.—(See *Blasie, Figures, &c.* a *Lithotomie* in 1814, on *Prostate* de la *Chirurgie*, *de Paris*, &c. p. 23.) In other words, the French staff turns more towards that side, as it approaches and enters the bladder. There may be some advantage in this construction, inasmuch as it tends to make the finger enter in the direction of the long axis of the bladder; yet a great deal more must be as to depend upon the position in which the staff is held, than upon its shape. Little doubt should always remain, as Boyer a staff is not to be easily introduced, because the operation will thereby be facilitated. The point, the most important part of the staff, is of course situated upon the convexity of the curved part of the instrument, or upon that portion which, when introduced, lies in the membranous part of the prostatic passage, and the bladder. It should always be made

very broad and concave, as recommended by Langenbeck and Matthews.—(See *Lithotomy*.) The movement of the prostate, at the end of the instrument, should be closed so as to prevent the further entrance of the finger, and prevent the back of the latter instrument from being retracted. English surgeons have been partly misled by Marshall and Schaeffer, for supposing that essential cancer; for certainly the most fatal injury may be done by the point slipping beyond the end of the staff.—(See *Lithotomy*.) But my own part, if I am from such of my countrymen, saying that another, is this, that the back of a proper staff the bladder ought never to pass out of or beyond the os of the urethra.

STAPHYLOMA. (*True staphylo.*) A growth from the being thought to resemble a grape, in that disease of the eyelid, at which the cornea loses its natural transparency, rises above the level of the eye, and even projects beyond the eyelid, in the form of an elevated, whitish, or pearl-colored tumour, which is sometimes smooth, sometimes covered, and according to Scarpa, attended with total loss of sight. However, staphyloma is either partial or total; that is to say, it affects only a part or the whole of the cornea; and in the first case, if there be not too much additional injury of the eye, a degree of vision may yet be left, and great relief of further improvement. The dissections of Scarpa's observations applying only to cases in which the sight is already destroyed, are useful for some important differences between him and other writers, who, in the position which they adopt, refer to the partial staphyloma, and cases in which the sight is not quite extinguished. Scarpa does not mention adhesion of the lids to the diseased cornea, with part of the definition of staphyloma; a point in which he differs both from Marshall and Boyer.—(Compare *Med. Chir. Abridg.* b. 2, p. 63.) However, Scarpa may be correct; for, though, as Mr. Wardrop remarks, "the internal surface of the cornea adheres to the lid in almost every case of staphyloma" (*Lectures on the Affected State of the Eye*, vol. 1, p. 301), for yet it does not invariably do so, the circumstance seems no essential part of the nature of the disease. In some instances, Mr. Wardrop has seen the opacity confined to one half of the cornea, generally the lower one.—(See *ibid.* p. 338.)

Scarpa observes, that staphyloma is often attended by the disease being after death, and mostly in consequence of partial staphyloma. It is also produced by the eyelid, yet never during its progress, nor during any stage of suppuration, but when the patient is dry, and even after the detachment of the vitreous body.

In a great number of subjects, says Scarpa, when staphyloma has attained a certain elevation above the cornea, it becomes stationary, or only increases in disposition to the rest of the eye. In other instances, the essential nature of the cornea enlarges in all its dimensions, and in such a disposition to the rest of the eye, that at length it protrudes considerably beyond the eyelid, in the partial staphyloma and detumescence of the patient.

This disease is justly considered as one of the most serious in which the eyelid is subject; for it entails not only considerable loss of sight, but it occasions, not added to the eye which necessarily results from the bulk and prominence of the staphyloma. In such circumstances, the essential nature of the eyelid to the content of the air and position of water is rendered to it; the friction of the eyelid; the incessant flux of tears down the subjacent cheek; render the eye painful and inflamed; the second eye is affected by sympathy, and the diseased eye at length ulcers, together with the lower eyelid and cheek at which it grows.

According to Richter (*Obs. Chir. fasc. 2*), staphyloma is generally formed without the swelling of the cornea being preceded by any of those morbid dispositions which are usually considered capable of weakening the texture and elasticity of the system; which, in fact, requires a much greater thickness than what is due to its natural state, and consequently staphyloma, far from being common within, is every where common and usual; though it ought to be quite the contrary, if the disease were occasioned, as some yet appears to believe, by an anomalous distension operating on the cornea from within outwards with absorption of its aqueous humor.

Scarpa thinks that Richter has generalized his doctrine too far, by not allowing any line of distinction

operator, that no one will be easily persuaded that the same instrument can ever prove of the least service in determining the size of the staphyloma. Scarpa is, in whole, in error as to, of that which purports to detach the eyelids and rest on the cheek. Under these circumstances, he believes that there is no effectual means of removing the progress of the disease, and removing the difficulty, but waiting away the staphyloma.

Mr. Gussie remembers Scarpa's application of Richter's method to young subjects sometimes, because the thickness of the cornea in them prevents the cause from quickly penetrating the anterior chamber, and considerable inflammation is brought on. (Diseases Surgery of the Eye, p. 115.) It is to be regretted, however, that Scarpa, when he tried Richter's plan, never made use of it to penetrate the anterior chamber, but merely to form and keep up a sort of leech, the exact principle of treatment which Richter himself intended.

Could Scarpa draw two blades of steel, viz. that with a fissure, and the removal of a portion of the cornea and adjoining part of the diseased cornea. (Ibid. p. 115, fig. 7.)

Though, says Scarpa, the first part, or that of the ligament, is at present abandoned, the sagacity of the operator will perceive it is giving a gentle and ligament through the lower part of the staphyloma, and for the purpose of tying or constraining the tumour, it is true, but of removing it, in order to fit the eye comfortably, what the staphyloma is to be cut off is a certain disaster. This use of a needle and ligament, which I observe, is introduced by Mr. Travers (Surgery, &c. p. 285), is strongly disapproved of by Scarpa.

With regard to the second method of removing the staphyloma, or that of excision, Scarpa thinks that sufficient attention has not been paid to the direction of the cut, and that the operation should be done in the centre of the cornea, and that the cut should be as much as half of the staphyloma, and that it should be as wide as a nail in size. As several surgeons of moderate magnitude are mentioned, Scarpa remarks, that the great importance of this precept was fully supported only by those who were when he had occasion to compare the advantages of Collin's doctrine, with the success in consequence of which result from the practice of cutting away the staphyloma directly as he has, and with the pain produced by a second operation, notwithstanding the success, as Wertheimer's history, always followed by acute inflammation of the eyelid and eyelids, violent pain in the head, redness, spasm, copious and extensive purulent discharges of the eye and eyelids.

The patient being seated, Scarpa directs an assistant to support his hand properly; then taking in his hand a knife similar to what is used in the extraction of the cataract, he passes the instrument completely across the staphyloma, at the distance of one line and a half, or two lines, from the cornea, or just of the margin, from the external towards the internal angle of the eye, and, by passing the knife forwards in the same direction, just as is done in the extraction of the cataract, he takes a semicircular incision downwards, in the most prominent part of the tumour. Having done this, he takes hold of the segment of the staphyloma with the forceps, and turning the edge of the knife upwards, he completes the circular incision of the apex of the tumour, in such a way that the detached portion is one line, three, or four lines in diameter, according to the size of the staphyloma. As a portion of the iris adhering to the cornea from the very commencement of the disease is commonly included in this section of the detached part of the tumour, as soon as the circular division of the apex of the staphyloma is made, then the crystalline, or its nucleus, issues from the eye, followed by a portion of the vitreous humour. In consequence of this evacuation, the eyelid is often so distended, that it can be removed by the eyelids, in which Scarpa immediately applies a splint of dry net, supported by a mucous bandage.

When the eye and eyelid seem to be painful, as done, and emit, as they necessarily do in the fourth day, the eye is to be covered with a broad mud-thick poultice. When things proceed in a regular manner, the swelling of the eyelids subsides about the seventh or ninth day, and perfect vision is seen in the position almost with the vitreous humour. The patient

afterward becomes thick and red, the patient feels great pain, and the eyelids are red and thick, and the eye is sore.

At this point, on gently separating the eyelids, the conjunctiva is found swollen, and red, and the pupil of the eye is seen like a whitish circle. This is usually detached on the seventh or eighth day after the operation, when the edge of the surface from which the staphyloma was cut becomes red, inflamed, and very discoloured, so that at last the wound is entirely closed. There is usually in the centre of the cornea, for a few days, a small fleshy prominence, resembling a little reddish papilla, which, after being marked a few times with the argenteo nitratum, continues and lasts.

So far, says Scarpa, the alarming symptoms from following this operation, that in a great number of cases the surgeon is even obliged, several days afterward, to stimulate the eye on which it has been performed, in order to make it inflame, partly by having it a long while uncovered and exposed to the air, partly by rubbing the circular incision made in the centre of the staphyloma, of which another circular portion half a line broad is removed, in order to facilitate the more abundant discharge of the humours, and the ingress of air into the interior of the eye, which now is backward and inflamed. As soon as inflammation has reached the interior of the eye, and suppuration has taken place, the rest of the cure regularly follows under the use of topical emollients, and is soon completed with all possible alacrity.

It should be particularly recollected, that Scarpa means the foregoing plan for indolent cases of staphyloma, where the growth is fairly lost, and the progress of the disease beyond position, or even emollient. Under other circumstances it is not advisable. Among others, Dr. Verch particularly objects to the removal of the apex of the tumour, as a destruction of all chance of the recovery of a degree of vision; a consideration, however, which would not exist in the highest stage produced by Scarpa. Dr. Verch also disapproves of letting out the vitreous humour in cases of staphyloma, as an endless source from which no permanent effect takes place, the liquor collecting again in a few days; a sentiment which is likewise expressed by Mr. Travers. (See *Verch on the Diseases of the Eye*, p. 121) and Dr. Travers, *Surgery*, &c. p. 285.) For the purpose of accomplishing the gradual diminution of the tumour, and bringing the eye into a state in which an artificial prosthesis may be used, Dr. Verch has employed another method recommended both by Richter and Beer, and the introduction of a string through the tumour. Beer confirms the statement of Scarpa, concerning the impossibility of removing the transparency of any part of the cornea affected with staphyloma. For the relief of a partial staphyloma, he makes the following application of the compressed air of Anthony, by means of the point of a needle-like brush, while the eyelid is well held asunder. The diseased part of the cornea is to be separated with a small sharp superficial scratch is formed, when every particle of the cornea may be immediately washed out of the eye with another large camel-hair brush dipped in water or milk. The operation is not to be repeated, until the subsequent inflammation has quite subsided, and the staphyloma removed. Beer continues all medicinal values, because their influence is to be put to rest which should be left undisturbed. (See *Verch on the Diseases*, &c. p. 121.) Mr. Gussie regards the treatment with caustic as only applicable to cases in which the eyelids, where the diseased tumour is thin, and the vitreous fluid is quite healthy. The knife, he says, is suitable in young or old individuals, where the staphyloma is entirely thick and hard, and the first of the eye been at least removed. (See *Verch on the Diseases of the Eye*, p. 121.) In the last resolution, indicated by the thick, indolent appearance of the sclerotic, which seems to be protruded close to the cornea by many narrow dilated vessels, and accompanied by a more advanced stage by a further out of possible pain in the inner chamber, leaving the vitreous portion of the eye might be removed, and with it the tumour, which may be a curious case. (P. 121.)

Went and success is often achieved by staphyloma, a protrusion of a piece of the iris through a wound in the eye. (See *Verch on the Diseases*, &c. p. 121.)

Dr. P. D. Hunter, *On Staphyloma*, Twining, 1788.

and generally trace the changes which take place by slow but sensible degrees in the nature of the secretion, from mucus to pus, and from pus back again to the state of mucus. This gradual discharge from various membranes in a case of inflammation may be kept up for months without those membranes appearing to undergo any other material change than a slight degree of redness and swelling. A low subsidence of activity is found not to happen earlier than a more time out of our examples of suppuration from mucous membranes.—(On Inflammation, p. 305, 306.)

The same well-informed writer afterwards proceeds to explain, that suppuration may be really produced in the case of catarrhs of the bladder, by whatever causes inflammation is that feature, and causes a separation of the catarrh. We have examples of this fact in bladders from catarrhs, and in vesiculations of the cuticle from superficial burns. In the vesicle covering a mucous blister as this be removed, and the catarrh exposed to the irritation of stimulating substances, pus will soon be discharged from the abraded surface. Suppuration can be kept up in cutaneous blisters for an indefinite length of time, as we see done every day in the management of pyæmic blisters. Ulceration is seldom observed in these cases; and, consequently, in cutaneous blisters, loss of substance is by no means necessary for the producing of pus.

If the cuticle be divided, as in a wound, or a portion of it removed, as in the excision of tumours, and either the air or any other external body be permitted to remain in contact with the divided surface, the process of suppuration is speedily induced in the cellular texture adjacent to the skin. After the hemorrhage which takes place from the small vessels has ceased, as coming of a fluid, at first coagulating serum, occurs, which is gradually changed into pus. But in this case, as Mr. Thomson has correctly observed, the surface of the wound is previously covered with a layer of coagulable lymph, which is penetrated with blood-vessels, and gradually mixed into the little red substance termed granulation.

Appositions similar, though slighter in degree, says Dr. Thomson, are observed in cutaneous suppuration; giving occasion to the eruptions of Sir E. Home, that in inflammation a vascular surface is produced previously to the formation of pus in a cellular membrane, and perhaps also in cutaneous texture. Dr. Thomson is inclined to believe, however, that no new vascular surface is generated in the inflammation of mucous membranes. Thus we see, that in the formation of pus in various membranes, cutaneous texture, and exposed cellular substance, no difference, no breach of substance occurs; but that, on the contrary, in two of these textures, the cutaneous and cellular, there is an addition made to the parts by the gradation of coagulable lymph, which becomes organized.—(Thomson, p. 325–326.)

SYMPTOMS OF SUPPURATION.

When matter is fully formed in a tumour, there is a remission of all the symptoms. The throbbing pain, which was before frequent, now goes off; and the pulsatile, erythematous, or more dull, constant, heavy pain. A critical subsidence, or paroxysm, as it is termed, takes place at some part of the tumour, generally near its middle. In this situation, a whitish or yellowish appearance is generally observable, instead of a deep red, which was previously observed; and in dissection of a fluid underneath may be discovered, on it a small elevation with the finger. Sometimes, indeed, when an abscess is thickly covered with scales and other parts, the dissection cannot be easily distinguished, though, from other surrounding circumstances, hardly a doubt can be entertained of there being even a very considerable collection of matter. An extraordinary swelling over the situation of deeply situated abscesses is a symptom which often occurs, and is well worthy the attention of every practical surgeon.

The discovery of the existence of deep abscesses is a circumstance of the highest importance in practice; and one which greatly interests the practitioner's pecuniary. In no part of surgery experience is more, similar cases of gravest error to him than in the present; and however simple it may appear, yet nothing, it is certain, more readily distinguishes a naïve from a skilful and extensive practitioner, than his being able early to detect collection of deep-seated matter. On the

contrary, setting off materially injures the character and prophylactic effect of a surgeon, as his having in such cases given an inaccurate or untrue prognosis; for generally, in evidence of this kind, the nature and extent of the case are at last clearly demonstrated to all concerned.

Together with the several local symptoms of the presence of pus already mentioned, may be considered the frequent shiverings to which patients are liable, especially in the first formation of acute abscesses. However, these signs are uncommon so as to be accurately observed, unless the collection of matter be considerable, or situated internally in some of the viscera.

In the progress of the fever accompanying acute inflammation (says Professor Thomson), rigors or cold shiverings not unfrequently take place, which recur at irregular intervals, and are in general followed by a hot fit, and slight increase of the febrile symptoms. These rigors or cold shiverings are general, systemic, when they occur in the progress of inflammatory diseases, and pus either is formed, or is about to be so, for inflammation according to injuries of the head, these rigors are often the first constitutional symptoms which give alarm to the unskilful practitioner. For they are generally, though not always, an indication that inflammation has already made a difference in our final progress. These rigors also accompany the formation of pus in the viscera contained within the cavity of the chest and belly; and are when the first symptoms which inform the practitioner that his endeavours to procure resolution have not been successful.—(See Thomson's Lectures on Inflammation, p. 320.)

Rigors, as Mr. Hunter remarks, are more common in the commencement of spontaneous lading systems, than in inflammations from external injury. They seldom occur in the suppurations which follow operations.

According to Sir A. Cooper, when matter is formed upon the natural surface of the body which are connected with vital organs, such irritation and disturbance take place; but when matter is produced upon the surface of a wound is a point not important to life, or upon parts of little vital importance, then its formation is often superseded by irritative fever.—(See Lectures, &c. vol. 2, p. 113.)

The constitutional symptoms which attend the formation of pus in the progress of chronic suppurations, are generally comprehended under the name of hectic fever.—(See Hunter.)

The pain attending what Mr. Hunter termed suppurative inflammation, is increased at the time when the vessels are dried, and this gives the sensation called throbbing, at which every one can easily be made sensible, by merely paying attention to the inflamed part. Perhaps this last symptom is one of the best characteristics of this species of inflammation. When the inflammation is arising from the inflamed state of the suppurative, the pain is considerably increased; but when suppuration has taken place, the pain is more degree subsides.

The pulsation then took place in the adhesion stage is now increased, and is of a pale scarlet colour. The pain when it was free, hard, and confined in the previous stage of the inflammation, now becomes still more enlivened, in consequence of the greater distention of the vessels, and the greater quantity of coagulable lymph thrown out.—(Hunter.)

THE END OF SUPPURATION.

The discharge of the living matter of an abscess into pus, and the power of this fluid in causing the dissolution, are opinions which are no longer maintained by any well-informed surgeons of the present day; and the use of such terms as "pus corrodes," "it is said," &c. expressions which imply an erroneous way of thinking, is very properly almost entirely discontinued in the language of every sensible medical man. If these notions were true, no one which a dissolving matter could be supposed from a continued dissolution. Such ideas probably arose from the circumstance of an abscess being a hollow cavity in the solids, and from the supposition that the whole of the original substance of that cavity was very the matter which was found in it. This was a very natural way of accounting for the formation of pus by

The dead parts separate, leave internal surfaces exposed.—(Haller.)

As every injury, or effect of outward violence under the skin, or external action, is more or less impeded in its surrounding air, the expansion of air in internal suppuration has been supposed, as a cause of suppuration, but certainly this is not the least effect of air, as pointed out above, for a suppuration would not form a wound, were it even contained in a cavity, by circumstances altogether, the air cannot possibly get to the parts, so as to have any share in raising these suppurations.

In most of suppurations, when the air is diffused over the whole body, the suppuration is the commonest lesion, as exposure or imperfect of some internal surface should be made, for the purpose of allowing the air to escape. A stronger proof that it is just an admission of air which makes parts inflame is that the cells in the soft parts of blood, and many of the cells and canals of their bodies, communicating with the large, and always containing air, never inflame, but as these cells are exposed in an internal ulcer, the stimulus of suppuration is given, then various these inflame, and their surfaces either form abscesses together, or produce pus.—(Haller.)

When the interior of an abscess is examined, the cavity which contained the matter is observed to be lined with a smooth, pearly-like substance, which is of a white, anhydrous, and has a strong odour, where it communicates with the atmosphere. This membrane-like formation has been termed the *pus* or *pus* of the abscess. It seems to possess the same as that of the abscess, to be the surrounding cellular membrane, which is itself likewise dense in texture, and more vascular than in the natural state. (Thomson's Lectures, p. 319, 320.) As this being closed by coagulating lymph, effused is consequent of that species of inflammation which Mr. Haller termed the adhesive. Thus, by the formation of a cyst, and the effusion of coagulating lymph in the cellular membrane around the abscess, the collection of matter is bounded and cannot become diffused, as it otherwise would do in the communicating cavity of the cellular membrane, like the case in suppuration.

Therefore like this diffusion of pus seems to occur in suppuration phlegmonous. But in this case (says Professor Thomson), the vitality of pus is lost, the position of the cellular membrane is destroyed; the dead and pus are converted into dry, white, anhydrous, and odourless substance; and it becomes extremely difficult to say whether any part of the pus contained in the destroyed cellular membrane has been formed in the cells in which it is contained, or has been absorbed into these cells, after being separated from the pores of the cellular membrane, the abscess themselves.—(Lectures, &c. p. 320.)

There can be no doubt that, after an abscess has received its suppuration, either at cyst, the secretion of pus is continued from the surface of the latter part vitally, as well as whatever degree of absorption of the same fluid happens to be going on. In fact, the cyst must be both secreting and absorbing surface. The circumstances which lead to the loss of this power, are the frequent rupture, or gradual removal of very large abscesses, collection of matter; the purulent changes occurring in the quantity and composition of the pus; and the speedy filling of the cavity with purulent matter again after the first contents of the abscess have been discharged.

Another thing which is yet a subject of controversy is, whether suppuration ever happens, unprovoked by inflammation? Professor Thomson, of Edinburgh, believes, that the stimulus operates on this point was first suggested by De Haen, of Vienna, but he thinks that much of the uncertainty of sentiment is the better part provided from the vague "action, continued and continued to the suppuration which necessarily characterizes the state of inflammation, and also with regard to the properties by which pus is to be distinguished from other internal fluids. Accordingly, in answer to the examples which De Haen has adduced to prove the formation of pus, without the previous existence of inflammation, he has himself occasion to remark the equality of coagulating lymph, and the mixture of purulent adhesions, phenomena, which are now known are produced by that state which Mr. Haller has denominated adhesive inflammation." But Dr.

Haller uses the term inflammation to express that state which we denominated suppuration or suppuration abscess; but in speaking of the cause of suppuration which he has adduced, he observes, that "it is many of them, no previous loss in consumption of substance could be perceived." An observation similar to this was made about the same time, or perhaps a little earlier, by Dr. W. Hunter, and is almost given of it in the second vol. of the London Medical Observations and Inquiries.

Mr. Hunter, though he endeavours to establish it as an ascertainable fact, that an suppuration takes place which is not preceded by inflammation, is of opinion, that collections of what he terms serous matter, resembling the pus, may form in various parts of the body without the previous existence of inflammation in the parts in which it is formed, and accordingly you will find, at page 200 of his Treatise on Inflammation, a chapter entitled "Of Collections of Matter without Inflammation."

Professor Thomson doubts, however, whether these collections of matter, said to be formed without inflammation, would not have been more properly denominated serous abscesses or chronic suppurations. I am disposed to believe (says he), that in whatever texture or organ of the body serous abscesses form, these inflammations will be found to exist. The phenomena, it is true, of inflammation, both local and constitutional, are modified by the existence of the serous abscess; but they are, I believe, always present in such a degree as to justify us in giving to them the name of inflammation, and in classing most, if not all local serous abscesses, among inflammatory diseases. When the violent swelling, of which Mr. Hunter speaks, occur near to the surface of the body, that part feels warmer than usual, every part in white swellings of the joints. The swelling also is either preceded or accompanied with some degree of pain, though, when the abscess is internal, the patient may not always be very acutely troubled by the present state of the part. When we take the parts also affected with serous swellings, we may say that they are vascular, that is, that all the symptoms occur by which the state of inflammation is characterized.—(On inflammation, p. 313, 314.) In another place Mr. Thomson admits, that the matter which is formed in chronic suppurations does not always necessarily resemble that which is formed in acute abscesses, yet he contends, that it does resemble both in its physical and chemical characters, as well as in the circumstances in which it is produced, that he can see no reason why it should not be called pus or a puriform fluid.—(p. 315.) For A. Cooper also indicates the serous doctrine, that the formation of matter is preceded by inflammation, which, he says, is healthy process is active, while in the debilitated and suppuration, it is often very slight, and the pus produced generally less perfect.

Sometimes there is even such a change of action that the pus is slowly diffused, being in serous abscesses serous and curd like, or even thick.—(Lectures, &c. vol. 1, p. 120.)

QUALITIES OF PUS.

True pus has certain properties, which, when taken singly, may belong to other sections, but which, collectively, form the peculiar character of this fluid, viz. globules swimming in a fluid which is coagulable by a solution of the acetate of ammonia, which on some occasions separates in, and, at the same time, a coagulum of inflammation. This fluid, like serum, is coagulable by heat. Pus also contains abundance of albumen; it never is poured upon pus until one solid part, which remains in the bottom of the vessel, be entirely deprived of all serum and globules, numerous portions of white are found remaining, and although not exactly of the same size, yet they have a great resemblance to pusules. They are composed of serum, fibrin, and globules; and were for A. Cooper. I have in human a theory upon this subject; I should say that pus was composed of the constituent parts of the blood, slightly changed in their character by inflammation.—(Lectures, vol. 1, p. 121.)

The colour and the consistence of pus are the two qualities which first attract the notice of every the most superficial observer. The colour differs from the light colour of this fluid being changed of very

small round bodies, each containing the globules of cream. The fluid in which the globules of pus swim, when first it is supposed to be the exudate of the blood, is a compound with just like the latter fluid. Pus is now possibly mixed with a small quantity of fibrinous (fibrin), as it partly dissolves after it is formed. However, the fluid part of pus is said to have properties which render it so. These being a weakly fermentous pus and milk, experimenters have been unable to ascertain whether the fluid of pus could be separated from the granular part of it, and had no coagulable matter effected in this manner; a solution of murexide of ammonia made the fluid part of pus coagulate, but not any more ignominious of material fluid; and hence it was concluded, that whenever globules were found remaining in a fluid coagulable by means of ammonia, the matter was to be considered as pus.

The properties which the white globules have to the other parts of pus, depends on the health of the parts producing the discharge. When the globules are very abundant, the matter is thick and white, and is called healthy pus; the secretion of which is, that the body which produced it is in good health; for those operations in the matter are so more than the usual of a healthy salivary processes going on in the solids, the effect of which processes is to produce the disposition on which both suppuration and granulation depend.—(Huxley.)

Pus is specifically heavier than water, and is probably about as heavy as blood.

Besides the above properties, pus has a sweetish, earthy taste, very different from that of most other secretions; and the same taste takes place, whether it is pus from a sore, or an irritative inflamed surface.

Pus has a weak in some degree peculiar smell; but this differs in different cases. Some diseases, it is said, may be known by the smell, as, for instance, a gonorrhoea.

Pus is in water; hence float. The commentators to water a suddenly troubled while, colour, induces gives the appearance of stringy portions floating in it. Mucous is said to be more rapidly dissolved by, agitated and then put in. It has also been asserted, that if water be added to such solution, the pus is precipitated to the bottom of the vessel; while the mucus, instead of being completely precipitated, forms a scum-like float.—A solution of murexide of ammonia dissolves both pus and mucus; but when water is added, pus is said to become separated, but not so true.

Though writers on chemical matters and precipitations have been thought of, but of the distinction between these two fluids, yet the simplest has been thought about and explained. It has been concluded that all animal substances, whatever, when in solution either in acids or alkalies, would be in the same order, and, therefore, that the precipitates would be the same in all. Calcareous earth, when dissolved in murexide acid, is in that acid, in the same state, whether it has been dissolved from chalk, limestone, marble, or calcareous bone; and precipitates from all are the same. Hence, the experiments have made its results almost certain, such as strychnine, carbon, carbon, iron, &c., and of (suspensions), such as suspended in water of an egg. All these substances were dissolved in sulphuric acid, and precipitated with potash. Each precipitate was examined with such care as to be fully cleared of the forms of the precipitates, all which appeared to be fully independent. The precipitates of strychnine had exactly the same appearance. The same experiments were made, when the above kinds of animal matter were dissolved by caustic potash, and precipitated with the murexide acid. A fleshy substance, such as the pig's bladder, composed of various ingredients.—(Huxley.) For additional details refer to the work of pus, and an account of those experiments by Dr. Thomas and Greenough, see the first volume of the Practice of Surgery, last edition.

Does not irritate the particular surface which produces it, though it may be very irritating to another. Hence, no suppurating surface of any species, and can be kept up by its own matter: if the fluid was kept in the case, no use of a specific quality, or producing matter of an irritating kind, could ever have been needed. This is similar to every other secretion of stimulating fluids, as the bile, tears, &c. when fluids do not stimulate their own glands to form, but are

capable of stimulating any other part of the body.—(Huxley.)

Whenever a cold disease attacks either the suppurating surface, or the constitution, the production of pus, pus comes, and the fluid becomes changed in some measure, in proportion to these medical circumstances. In general, it becomes thick, thicker, and more coagulable, and purulent parts of the matter of the blood, as in the case of many other secretions, under similar circumstances. Hence, in this form usually appears to improve to put in the degenerated blood. The healthy part of matter has more of the blood, and the quality of the coagulable part is improved by a solution of murexide of ammonia. It has also a great proportion of the albuminous parts of the blood, which are soluble in water, such as milk, and it has a great tendency then to be put in, becomes putrid. Such a healthy matter may even be irritating to the surface which produces it.

The secretion of matter is often supposed to be long, while the constitution is thus disturbed, a case will frequently appear almost dried up; but in the production of the blood, its surface will change some part in some disease. This is a fact which every young doctor must have noticed. A smaller check to the secretion of pus is also produced when a sore, or the parts immediately around it, are attacked by fresh inflammation. The diminished quantity of pus is likewise changed in its quality, so it becomes a thin fluid, or a thin fluid, composed of serum and red particles.—(See A. Cooper's Lectures, p. 122, vol. 1.)

The discharge, when of an irritating kind, is more stimulating to the suppurating parts with which it comes in contact, than to its own secreting surface. In the manner it frequently produces extension of the skin, and ulceration. Thus the tissue promotes the only in the thick, in consequence of the pressure of cells which they contain. From this effect, water has been used to compress, equally which it does not; the more pliable which it possesses being that of retaining the parts which it touches so as to cause their absorption.—(Huxley.)

When the vessels have lost the power of producing good pus, they also lose much or both the power of emitting granulations. This may depend on their distance from the diseased surface, and hence when with vessels should possess, in order to be qualified to the performance of these two operations.

Thus, from several considerations, would appear to be general to have a greater tendency to production than the natural juices have; but, perhaps, this is not the case with pure pus, which, when first disengaged from an abscess, is commonly perfectly pure. There are, however, some exceptions to this; for thus depend on circumstances entirely foreign to the nature of pus itself. Thus, if the abscess has had communication with the air while the matter is contained in it, or if the collection has been so near the surface of the skin, as to have been infected by the frost, but we cannot wonder that the matter should become putrid. When blood is mixed with pus, when clots are found with it, when the parts forming the seat of the pus are in a gangrenous state, from an inflammation, when the matter has a great tendency to putrefy, then the pure pus disengaged from such abscesses is highly impure. Pure matter, though slowly formed, is capable of change by extraneous addition, it is mixed with a variety of matters and impurities. It is more susceptible, than we find it is putrid, as it is more for weeks, without having undergone any putrefaction. These qualities, however, only being in pus, put, if a healthy one, however, the matter will become from it, though combined with extraneous blood or dead white, because such matter putrid, and much more irritating than the discharge formed from the abscess of the ulcer.—(Huxley.)

In the preceding paragraph it is stated, that matter frequently remains unchanged in its nature for years. This statement of Huxley's is not exactly correct; for it is well known, that the surface of the cavity of abscesses are always changing, as well as the matter; consequently, there must be a continual renewal and change in the contained matter.

When there are diseased bones, or other extraneous bodies, exciting irritation, sometimes even to a great degree as to make the vessels bleed, and when blood

them, this matter is always found to be very offensive. This state of the discharge is very much of a diseased look.

The discharges of an unhealthy sore blacken silver probes and preparations of lead. This effect is noticed, by Dr. Crispin, in the sulphuretted hydrogen gas generated in the matter.—(*Phil. Trans.* vol. 51, ser. 1, 1796, p. 263.) Further interesting observations on the nature of pus may be found in an Essay on the Difference between Flegm and Pus, by Dr. Boerhaave, also in Dr. G. Fournier's Paper in *Philos. Trans.* 1811.

USE OF PUS.

By some it is supposed to carry off humors from the constitution. Suppuration is sometimes regarded as a constitutional disease changed into a local one, which constitutional disease is discharged, or thrown out of the body, either in the form of pus or together with this fluid. Critical diseases have been thought to be cases of this sort. Suppuration has also been imagined to carry off local contagions from other parts of the body, or the local principle of derivation or resolution. For this reason some surgeons are often made to repeat parts before other ones are done up. Suppuration is sometimes excited with a view of making parts, such as indurated swellings, absorbent and putrid; but I have observed to absorb and to disengage the solids is concerned in the production of pus.

A secretion of pus is looked upon as a general protection of nature to all the cutaneous diseases. Hence, nature will make us keep off suppuration as well as local diseases. However, the use of pus is perhaps unknown, for it is found most profusely from healthy sores, and in healthy constitutions; and large discharges from parts not very essential to life produce very little change in the constitution, and so little upon being healed up, whatever secondary support to the system.—(*Hastie*.)

This is certainly the case with many old ulcers, the suppuration from which seems to have little or no effect in improving the health. Now in these few rare cases to be afraid of healing such ulcers, when possible, for a worse disease should follow from the stoppage of a discharge to which the system is supposed to be so habituated that the continuance of it must be essential to health.

Every one knows that when there is no interference at all, that is, when the surface of a sore is left uncovered, the thin part of the matter evaporates, and the thick part dries and forms a scab. Nature, therefore, seems to have designed, that use of pus should be to make a cover, or protection for diseased surfaces. But I cannot agree with what has been asserted (*Hastie*), that the natural healing of a sore under a scab takes place more quickly than when surgical dressings are employed.

On ulcers, it would appear from modern physiological observations, "the coagulated pus is rendered soluble by the saturation of its carbonic acid, and these (pus, or serum, are immediately filled with red blood, and thus connected with the circulation." If this point were established, the lowered blood economy, that these would then be able to diffuse is making out the suppurating stages, by means of which the coagulated pus afterward becomes organized.—(*On the Generation of Pus, in Crustaceous and in Fish, in Phil. Trans.* vol. 60, p. 262, Lond. 1812.) These observations are curious, and ought to have been noticed in the source of pus, to which they were immediately added. I do not imagine, however, that nature will in nature send further the secrets here referred to.

Among the secondary uses of suppuration may be mentioned, opening a communication between a disease and the external surface of the body, forming a passage for the exit of extraneous bodies, &c.

TREATMENT WHEN SUPPURATION MUST TAKE PLACE.

In cases of inflammation, arising from accident, but so circumscribed that we know suppuration cannot be prevented, the indication is to moderate the inflammation, which, if the powers are great, and the injury done constitution, will probably be very violent. If the constitution should also be much affected, certain general means are proper, such as bleeding, purging, and assuaging remedies. While the constitution is

severely disturbed, suppuration cannot take place in the most favorable manner. In these cases, then, such medicines as produce a gentle perspiration greatly relieve the patient; for instance, the pain, *peran. comp.*, *mentha. p.*, *pepp.*, *mentha. p.*, *mentha. p.*, &c. Opium may produce a temporary dissipation of action; but they do not always have this desirable effect, and in some constitutions they increase the general irritation of the system, and seriously aggravate the inflamed matter.

The applications to inflammations which are leucopurulent and form an abscess commonly need not, postures and compressions. These, however, appear to be applied without much critical success in dissipation; for they are applied before suppuration has taken place, and when this system is not done up, and they are also applied after suppuration has taken place. With respect to suppuration itself, abstracted from all other considerations, the indication cannot be the same in every case; but if postures and compressions are found to be of local service in the two stages of the disease, there must be observing, constant to both for which they are of service, independently of simple suppuration. Postures are useful when the inflammation attacks the skin, either in the first instance, or after an abscess has approached so near the skin that it becomes secondarily affected. This benefit appears to arise from the skin being kept soft and moist. Such is the use of a posture in inflammation, either before or after suppuration, until the abscess is opened. But when postures and compressions are applied to inflamed parts, in which we wish to avoid suppuration, reason and principle will not justify the practice, though such applications may be preluded by experience to be very proper.—(*Hastie*.)

TREATMENT AFTER SUPPURATION HAS TAKEN PLACE.

When suppuration cannot be stopped or removed, it is in general to be protected.

How far suppuration can be safely prevented by medicines or applications is questionable, but it is generally possible, and for this purpose supporting cataplasms and blisters, composed of the warm gases, acids, &c. were formerly much recommended. Mr. Haastie doubts whether such applications had any considerable effect in the way intended; for if they were given a time, they would hardly increase the discharge from it, and perhaps even diminish it. However, in many cases in which the pus is not evident and hardly admit of the inflammation, in consequence of which a perfect suppuration cannot take place, stimulating the skin brings on a more salutary, and, of course, a quicker inflammation. Thus the antiseptic treatment and blocking the skin over chronic swellings and abscesses, are sometimes indicated.

These applications have been found, however, to bring the matter more quickly to the skin, than in the most rapid suppurations. This effect has been mistaken for an increased formation of pus; but this consequence can only follow in cases in which the lower surface of the abscess is within the influence of the skin. The accelerated progress of the matter to the surface of the body arises from another cause, viz. the promotion of absorption to the part, because the collection of matter and the cure.

Essential postures are commonly applied to inflamed parts, when suppuration is known to have taken place. These can have no effect upon suppuration, except that of lessening the inflammation, or rather, making the skin more dry. The inflammation must have reached the skin before postures can have much effect, for they can only affect that part. The use of the patient, however, should be considered, and we find that compressions and postures are often beneficial in this way. By keeping the article about the wound, the sensitive operations of the parts of the part are worked. On the contrary, if the inflamed skin is allowed to dry, the inflammation is subdued; and as suppuration is probably prevented by the above treatment, it ought to be put in practice. As usually excepted, unless the suppuration should be so severe as the patient can bear without inconvenience.—(*Hastie*.)

The local treatment in phlegmonous abscesses (as Professor Thomson observes) is still more simple than that by which we endeavour to prevent resolution. It

her and the skin at this part is the venous region against the jawed. If an abscess is rather recently formed, and points in a place which is kinder than where the radiation lies, it is proper to make the opening where the cervical sinus is, as the point, for pointing, appears. Thus, if an abscess should form in the tissue of the human jaw and point in the upper part, which is often the case, it would be improper to cut through the lower half of the maxilla, in order to render a passage for the matter in that direction. If an abscess should form on the upper part of the face, it would be wrong to make an opening through the side of the face to get at the most dependent part of the abscess; the better thing would be a depth of several parts, a great many small ones would be destroyed.

Where the choice does not point to a separating situation, as in the instance just cited, since the point where the matter threatens to open a passage is likely to be the future opening, and this situation is deemed inadvisable to the feeling of the deep part of the subject, it is generally best to let the collection of matter first burst off itself, and then allow the opening actively to recover. By allowing otherwise to burst spontaneously, the opening is not so open to him as if made by an act, and, therefore, is better in such situations—*(Myer.)*

In most cases, it is queer, advantageous even to call through a certain thickness of paper, by the aid of drawing a depending spring, then to make an opening where the pointing appears, that is, where the point is thickest, and the writer restored the surface. This remark is highly worthy of remembrance, when there is to be done the thickness of matter at the depending place, and when the parts to be divided are not important ones. Collections of water beneath the folds of the forehead and high particularly drawn attention to this disease, as they constantly point where these operations are possible are thickest, not where the matter can be readily escape.

Abstinence is the element of the positive abstinence should also be spread in a large situation.

SUFFICIENT NUMBER OF OPENED ARCHIVES.

All Muslims will naturally have of this—why, because the justice is obvious, and in general, they would be allowed to take this station. There are, however, as I have already explained, particular circumstances which require to be fully ascertained; but, with the skin and the station is very thin, it is not of great consequence whether the cause be permitted to stand or not, if it is opposed by the majority.

When there are any larvae, it is perfectly necessary to open them by air, whether they have been discovered or not, for the natural opening will seldom be sufficient for the maturation of a worm, and although some is sufficient for the free discharge of the matter, yet these worms will lead a more miserably tedious life, spending it in doing for the thin skin over the cavity of the pharynx, and, therefore, without sympathy with the parts underneath. (Mason.)

Attenborough will be surprised either by an increase, or by a lack of an upsurge with climate. "In the latter phase, however, many very young organisms—the sort of animals that I just briefly alluded to with my adaptations when they are first formed by a single neuron—upon a further increased partial gress must enter part. It is more like in a little, and the organism can never forget the importance of the critical, so accurately as to destroy exactly the parts which he wishes, and not more. It is the entire he can't keep deep enough, the lower part, after all, is gone. Critical, also, however, after its application, a distinguishable state, a combination of some importance in keeping answers about the critical level in fact. To these young organisms we have to add that the signal is very frequently seen or is clear, indicate days in a season, delivered.

While there is a redundancy of skin, at times there is a good deal of it thrown, however, absorbing up to with cosmetic will manage, perhaps, as well as an incision. The application of cosmetic only also sometimes be advantageously resorted to when there is a good deal of broken tissue around a small ulcer.

The side view pattern, or the pattern alone, is the first pattern for making the skirt. The pattern is first to be drawn with a piece of muslin paper, which has a portion cut out under the curve of the same figure and size as the opening intended to be made in the muslin.

The first step of making the ocker is to dip the end of the capsule in water, and to rub it on the part of the skin to be treated. The dried substance is then to be repeatedly washed off with warm water, the plaster is to be removed, and an ocherous pellicle appears.

In almost all cases, it is better to use the insert, or double-weight blanking. Either of these instruments opens the abdomen to view, and with less pain than results from the use of craniocly; it necessitates no loss of substance, consequently a smaller cicatrix; and by using it the opening may be made in the most advantageous direction, and of the exact size required.

DECLASSIFIED AUTHORITY: 48 CFR 1.101-2.6

When an alcohol has been of itself, and it is time necessary to change the ageing, the only thing responsible is to keep the outstanding parts clean. The neutralization of the same kind of positive which was necessary used is, perhaps, as good a practice as any; and when the treatment, nothing from the fermentation is over, and a product may be made that of, instead of the

For an address opened by a cutting instrument is both a wound and a cure, and portends some of the nature of a fresh wound as prescribed to the thickness of the point of it. Hence, it is necessary that something should be put into the opening to keep it from healing by the first intention. If it is hot, it should be stopped by a compressive, which will remove better than that alone, as it will inhibit of being taken out again. This is accomplished, by some such means should be dressed the next day, or, at least, on the second day, in order that the life may be discharged safely. When the end of the opening has perforated, which will be in a few days, the tissue dressing may be as simple as possible, for nature will in general complete the cure.

If the discolor has been repeated with caution, and the slough-like surface were cut out or separated if thick, the wire can be reprinted satisfactorily as a photographing copy, and fixed immediately.

[illegible][illegible]

more can be expected from such a mode of study than mere imitation, or blind experience. Indeed, some people have affected to oppose surgery as an art, to medicine as a science; and if these professions were fairly founded, the former would certainly be regarded as a more mechanical occupation. But it is not very easy to comprehend the grounds of such a distinction. The internal and external parts of the body are governed by the same general laws during a violent attack, and if an internal part be attacked with inflammation, the symptoms and effects will bear a great similarity to the same disease situated externally; nor are the individuals of one sex, in general, materially different. If he observe, therefore, he acquires a knowledge of the laws of nature; he knows what is known of the state and mode of nature. In the production, progress, and termination of surgery it therefore results as easily the title of a scientific practitioner as the uneducated physician. The practical parts of physics and surgery are very differently classified; but their theory and principles are indivisible, since they truly constitute one and the same science. — (*Principles of Surgery, Preface.*)

As a second Professor lectures, the flag is between physics and surgery are not very precisely separated, and he expresses his opinion of the physician and surgeon, saying in those words have existed, are just but very imperfectly defined. "The most essential acquaintance with the symptoms, progress, and termination of the various internal affections to which the human body is liable, must be sufficient to convince every student of medicine, that there is but a slight dissimilarity, if indeed there be any, for this distinction in the nature of the disease which these practitioners are required to treat, or in the medical treatment by which the disease themselves may be cured or relieved. Experience has long shown that the most internal morbidities are not only required in a large proportion of the diseases which are regarded as merely surgical, but also, that there are few diseases which fall under the care of the physician, in which medical affections, requiring the talent and practical skill of the surgeon, do not frequently occur."

The treatment of febrile and internal inflammatory diseases, it will be observed, belongs exclusively to the province of the physician, whereas the distinction between physician and surgeon has been introduced, and is strictly observed; yet, in some species of fevers, and in all febrile inflammatory diseases, blood letting is often the principle, if not the only remedy that is required. But this is an operation, however urgent the necessity for it be, which does not engage the physician's hands, and from the line of separating the province of the profession will not perform. Retention of urine not infrequently takes place in dyspepsia, febrile diseases, and even in an affection which does not always point to the use of external remedies; but such an affection also, from the painful symptoms which it frequently excites, as well as from the danger which it sometimes, that will not admit of delay. When internal remedies, therefore, fail in relieving the patient, the urine must be speedily opened off by means of a surgical operation; otherwise inflammatory, morbidities, and rupture of the bladder may necessarily ensue. Febrile and internal inflammatory affections therefore not infrequently in the formation of fluids, which it is necessary to cut by a surgical operation; and otherwise, venous stagnation, and there are fevers, which require the aid of the surgeon. In gonorrhoea, which is attended with severe febrile diseases, from being long shut down to their beds is one position, some of the parts of the body, then, which they rest, occasionally require a division to mortify, deeper or shallower portions of the soft and subjacent cellular membrane, breaking dead, separate from the living parts, and move the fluids which are but too often the subject of unavailing surgical practice. To surgery in the different stages of the species of mortification, from its first commencement to the complete separation of the dead parts, and the formation of a new skin, the appropriate external and internal remedies, require a proper share of surgical skill, if this can reasonably be expected in those who assume a profession solely of physic. Unhappy, therefore, must be the lot of that student, who in circumstances similar to those which I have mentioned, has the misfortune to have for his sole medical attendant a physician ignorant of surgery.

"But (says our Professor Thomson) if a knowledge of surgery is necessary to the student who intends to practice physic, the knowledge of physic, on the other hand, is equally necessary to him who intends to devote his attention exclusively to the profession of surgery. For, indeed, there are some dangerous diseases, which are not, in some period or another of their progress, unaccompanied by morbid affections of the same nature with those which fall properly, and most frequently, under the care of the physician. It will only be necessary to mention, as examples of these affections, the symptomatic fever which attends inflammation, whether this affection has been induced by external injury, or has occurred spontaneously in the body from internal disease; the hectic fever, supervening to long-continued processes of suppuration; the hectic state, and other morbid affections, which are sometimes brought on by the too sudden and ineffectual use of mercury to drive fevers, and the various disarrangements of the digestive organs, which are sometimes the cause, and at other times the consequence, of local diseases; the nervous affections, such as apoplexy, palsy, hysteria, paralysis, and mania, which arise not infrequently from injuries of the head; and locked jaw, or trismus, which is never classed by physicians, as it very rarely is to be induced by surgical means. These are morbid affections, the proper study and treatment of which, when they occur in internal diseases, are supposed to belong to the physician, rather than the surgeon; but occurring very frequently, as they do, in surgical diseases, and always modifying or aggravating the effects of these diseases, ignorance of their nature, relations, and modes of cure, is not only inadvisable, but highly criminal in the practitioner who attempts to undertake their treatment." — (*Thomson's Lectures on Febrile Diseases, Introduction.*) Also *J. R. C. Thomson, Treatise on the Diseases of the Nervous System, and on the Diseases of the Head, 1841.*

From what has been stated, I think it very certain that there never can be a complete and sensible division of the healing art into physic and surgery; and that all attempts to distinguish the morbid diseases and injuries of the human body into medical and surgical classes, are, in a great measure, to be divided by saying that the medical treatment of practitioners, rather than by any rules or principles which are at all necessary.

Mr. Lawrence joins all the most judicious practitioners in believing that the line of demarcation between surgery and physic cannot be easily traced; and he considers the distinction between them to be a mere matter of arbitrary usage. He employs the word surgery in its constant acceptance; understanding it to include all injuries of all kinds; Effly, The greater part of external and local complaints; Effly, Local internal affections, as produce changes from within externally; for example, alterations of figure, colour, or consistence; Effly, All cases requiring unusual topical treatment, operations, or unusual proceedings of any kind. This view coincides very much with the catalogue of diseases treated of in the present work; yet, such is the difficulty of separating surgery from physic by any verbal definitions, that every man of experience will immediately involve various exceptions to some of the foregoing principles of classification. Thus scurvy, or dysentery, which is an internal disease productive of change of figure, and often requiring an operation, is usually regarded as a medical case.

In the earliest periods, the same men cultivated the whole field of medicine. The writers of Hippocrates, Galen, Celsus, Placius, Aeginetia, Avicenna, &c. prove that the Greeks, Romans, and Arabians never had an idea of the human body being susceptible of only two classes of diseases, one of which formed the province of physic, while the other constituted a separate and distinct science, called surgery. They had no conception of two systems of pathology, one applicable to the exterior, the other to the interior parts of the body. They knew, as well as the best informed practitioners of the present day, that though each organ has its particular function to perform, no office is not independent of, but closely connected with the use and perfect state of other organs. Hence, as Mr. Lawrence has noticed, the expression of Hippocrates is perfectly consistent with the modern view of the human body, although various in structure and

sedious cultivation of comparative anatomy, that their industry adds no improvement in surgical science, whatever made, to enrich their nation; and that surgery is greatly indebted to them for the advancement of the diseases of the eye.

On the continent the Royal Academy of Surgery at Paris was long considered quite as the solar light of this branch of science. Nothing, indeed, contributed so materially to the improvement of surgical knowledge as this establishment, a noble institution, which, for a long while, gave our Englishmen better advantage even as in the cultivation of this most useful profession. The French literature, which, by a fatal abuse, consisted in the same pretensions both useful and pernicious sciences, did not spare surgery beneath its selfishness, in which credulous and trifling had been so long misled for the benefit of mankind. The various dissertations published by the illustrious members will serve as a perpetual memorial of the energy, ability, and success of which its objects were pursued, and varieties lesser practitioners will reap from the pages of its members the most valuable information. Although the Academy was deprived of the services of Lenoir, who died at an early time before its expiration, it yet kind at this period several successful works of continuing its labours, and supporting its reputation. Sabatier, Desault, who may be regarded as the Father of France, Chiquet, Lenoir, Pons, Dubois, Pons, Blandin, Pons, &c.

The Academy of Surgery in France was succeeded by virtue of the Ecole de Médecine. Desault, who had been almost a stranger in the country, became quite the leading physician in the latter. Several things recommended him strongly to the recognition and admiration of posterity; the character of his mind which he introduced into the study of surgery, the important studies of anatomy which he devoted to the treatment of fractures, a noble courage in his profession, which he knew how to employ in all his pupils; his liberal lectures upon surgery, which were the first ever delivered; and the boldness and simplicity of his mode of operating. Indeed, such was his genius, that even when he printed only methods already ascertained, he did them with so much substance, that he rather appeared as the inventor of them. From the Ecole de Médecine have issued Blandin, Boyer, Deschamps, Dubois, Lenoir, Moreau, Lallemand, Petit de Lenoir, Petit, Blandin, Chiquet, &c.

Among the public institutions in Europe for the improvement of medical and surgical knowledge, the general Medical and Chirurgical Society of London certainly stands pre-eminent, whether the reputation and number of its members, the importance of many of the papers which it has published, or the extended value of its library, be taken as the criterion of the character which is here assigned to it. Many of the facts which it has collected and published are of considerable practical importance, especially those relating to the subjects of aneurism, hæmorrhage, the diseases of the puerperal, in the bladder, and that kind catalogue of all diseases, especially in the library, which is that of the Royal College of Surgeons, is the most select, valuable, and complete collection of medical literature in Great Britain, more especially with reference to modern works, is continually receiving additions, both by large purchases in books and serials, and by the numerous donations of its members and others. The numerous and distinguished which such a society always maintains render the latter a most valuable resource of the profession, and that full to be attended with the most beneficial effects upon medical science in general, a person had no doubt of assistance in this kind alone, the spirit of inquiry is kept from flagging; and every individual who becomes a member of this society is enabled to make use of it in the world, with all the regularity which is important in any direction. My this observation, I do not mean that it will always appear in print directly after the communication to the society, so that to a circumstance which is so very much dependent upon those being as not a sufficient quantity of interesting matter as the Society's permission to be an additional part of its Transactions; but the very reading of the papers at a public meeting gives it immediate authority in the profession, and if it is thereby and worth to be given, it is certainly very great attention.

The measures of Lenoir, who guided surgery, pre-

viously constituted in the advancement of physiological science. His mind, richly stored with the positive facts which he had learned in the study of surgery, conceived no less a project than that of searching out the whole system of medicine. Some courses of lectures upon the materia medica, internal clinical medicine, and morbid anatomy, constituted this vast design, which was frustrated by a premature death. Indeed, as a physiologist and man of very critical genius, he may be considered as the John Hunter of France; but his qualities were of a different type, and hardly admit of comparison with those of Hunter, whose investigations were not limited to man, but extended to the whole chain of animated beings. Hunter died in the midst of his labours, and, in dying, his greatest effort was that of not having exhausted them. His example, says Richardson, gives most conspicuously when liberally always facilitated, and every man of scientific habits, how indispensable the study and every the practice of surgery are to him who would wish to be a distinguished and successful physician.—(*Narrative*, Chap. 4, p. 25.)

In the course of the last thirty years, great and general improvements have been made in the theory and practice of surgery.

Before the time of Mr. Hunter, our ideas of the general disease were surrounded with absurdities, and it is to his laboratory and the plain facts told before the profession by the late Mr. Ross, that the art is in an improved degree indebted for the improved discrimination and reason which have prevailed, both in the doctrine and treatment of the complaint. It must be confessed, however, that much yet remains to be made out, respecting the nature and treatment of syphilitic disease. Now I mention a greater point of the truth of this matter, that the remarkable change of practice as regards the syphilitic hospital in London, whereby being not contented in not using this specific at night or in less cases, for which this medicine a few years ago was always deemed indispensable? Nevertheless, taking all the characters of primary venereal disease, were also not to be made of simple diseases and diseases; and the necessity for violent treatment in all cases, begins now to be generally discredited. In short so different is every stage from what it used to be, that many persons are tempted to suppose the nature of the venereal disease truly altered.—(*See Venereal Diseases*.)

Recent to the student, an equally curious and interesting disease, more not well known of late Mr. Hunter published on the venereal disease. Until this time we were acquainted with a good practical method of applying mercury to the venereal disease, a method which has been well developed in the world, however, invented by Sir Robert Ross. The latter gentleman looked, but taken a very scientific view of the whole subject, and perhaps his only error is that of not having sufficiently valued his own insights of treatment.

In modern times venereal diseases, those common affections in every country, have received highly interesting elucidations from the labours of Drs. Casper, Richter, Sir Astley Cooper, Hey, Gendreau, Henschel, Scrup, Lawrence, Langenscheidt, Ciquet, &c.

The treatment of injuries of the head has been especially improved by Quercy, Le Dant, Petit, Hill, Denham, Denay, Hey, Abernethy, and Brodie.

The diseases of the vertebrae, which concern the primary of the limbs, formerly always killed the patient; but the method proposed by Mr. Pett is now frequently productive of considerable relief, and sometimes of perfect cure. The diseases of the joints in general may also be said to be at present viewed with much more discrimination than they were a very few years ago, and this great respect to better and more numerous valuable efforts are mentioned by Mr. Brodie, which keep to a trifling degree upon the whole anatomy, the study which he of late has been so much occupied with this part of surgery, will yet be the result of bringing to light some useful facts and observations relative to the pathology of the joints.

In the time of Mr. Pett, Sir James's patients afflicted with hydrocephalus were recovered; for soon after a first opening had been made, according to the method then in vogue, the disease was so severely cured with no further irritating fever, which hardly admitted of any control. Mr. Abernethy mentioned that much of this risk might be avoided by making only a small

Diseases of Antrix and Vagina, first published in 1815, a work which reflects great credit on English surgery, and contains practical precepts far superior to those of *Keegan*. A new edition of it, enriched with later observations and the latest experiments and reflections of the present author, I am happy to announce as being on the point of publication.

In the modern practice of surgery, a variety of old prejudices are gradually vanishing. Physicians look no more upon us, we are regarded as a necessary remedy and specific for nearly all cases of dyspepsia; and in these and many other instances, a cure is procured without any incision, and in cases beyond all modern cure. But the false idea that this treatment has any specific effect in effecting absorption, no longer binds the hands of the most superficial practitioners. The latter however are too ready, for the influence of food, and the strength can be rationally explained from the vegetable substances, and consequently cannot be the source of nutrition in the stomach, which can be made to manifest in the stomach.

The valuable discovery recently made in France, relative to the nature and character, the essential parts of Puerperal fever, assigned to a very small corpus, will lead to great improvement in the mode of prescribing this medicine in every case where it may deserve trial.

At the present day, the subject of mortification opens to us a new field for investigation, of the first rate importance. Every surgeon is aware that when a limb is deeply affected with mortification, amputation is absolutely necessary. This is generally acknowledged, but the period when to operate has, since the time of Mr. Pott, only been ascertained when the mortification has manifestly spread, and a line of separation is formed between the dead and living parts. All observations in which the disorder was in an ascending state, were left to their fate. In the most of the old surgeons, unfortunately inclined to deviate from this point: but as they did so without any discrimination or knowledge of the genuine character which ought to form an exception to the general rule, their all success cannot, as it is a just argument against the plan of separating earlier in a certain disposition of the case.

Now, if modern experience prove that many limbs may be saved by a timely performance of amputation, under circumstances in which it has until lately been generally condemned, it would be allowed that the recommended incision will be one of the greatest improvements in the practice of the present time.

For avoiding the consideration of this question, and resisting its design from the better path, the world is much indebted to that eminent military surgeon, Baron Larrey. His different and successful operations, and the success of those usually taught in the schools, the whole mortification will sufficiently prove.

Connected with this topic is *Suppurative Gangrene*, a name which denotes, more to be pointed out, as having received considerable attention of late years, and being much better understood now than the efficacy of the solution of pus, and strong acids, and has been so completely proved by the observations of *Boissac* and *Wohlfart*.

In the treatment of compound fractures, the success and importance positive suggested by Dr. Pott of Philadelphia, is much particularly noticed: various successful trials have been made of it in this country, and France (see *Notes des Chir. Fr. vol. 2 and 7*) and *Anger's Treatise des Maladies Chir.* as well as in America, and, though liable to failure, it is yet entitled to be regarded as a valuable addition to the plans already devised for these cases, which sometimes render the patient a tedious cripple during life.

The inextinguishable nature of Dr. Jones on *Hæmorrhage* has now produced quite a revolution in all the principles by which the surgeon is guided in the employment of the ligature for the purpose of bleeding, and the cure of hæmorrhage. Instead of thick elastic ties, small fine silk or thread are now generally used; and so far as the practitioners have been fearful of tying arteries too tightly, but the ligature can then, that it is now a particular object with him to apply the silk or thread with a certain degree of force, in order that the larger part of the vessel may be divided, so that he not draw the edges of the surrounding tissue within the artery, and impede the progress of the

arterialization, cannot be expected as a matter of certainty, and secondary hæmorrhage is more likely to occur. But in order to convey an adequate idea of the beneficial changes which Dr. Jones's observations are leading to produce in practice, I have been carried in the course of this paper, to give a summary not so much of the results of all his interesting experiments.

Dr. Jones, in several, small papers, deserves here to be also mentioned with particular honour, were he not probably the earliest writer that had the stroke on the advantage of tying the arteries with very small ligatures; one of the greatest improvements in the treatment of wounds and in operative surgery. "My experience and reasoning," says he, "led me to recommend a small ligature, and its utility and success were not left to conjecture, but clearly laid down; and the introduction of this practice to surgery is, I think, unequivocally due to me." Dr. Jones did not apply his small ligature to equine or the human body; and the practice of using the small single ligature was not adopted at the Edinburgh Hospital, in which all his experiments were made until the appearance of the following Essay on the Ligatures of Arteries, which was sent to the editor of the *Edin. Med. and Surg. Journal* in 1820, but was not published until the 1st of April, 1826. — See also the *Ligatures de Jones*, 1824. In justice to Dr. Jones I should mention that his book was published in 1820.

Wounds being very small, firm, round threads, instead of sows, the tapes or cords, as they are called a few years ago, whose modern surgeons have suspected that such would pull down from cutting off both portions of the ligature close to the hæmorrhage application, the removal of the ligature, &c. No one has failed so much as Mr. Lawrence upon the propriety of examining further the merits of this innovation. If we had effectual means for relieving a patient of hæmorrhage without the use of the knot, by the use of silk, catgut, the knot and suture on the artery, the practice will have a considerable improvement. The thread may then be brought together at every point; the quantity of hæmorrhage, water in the part will be lessened to almost nothing; the danger of any other affection will be reduced in proportion to a second cause of pain and irritation is diminished; and the chance of accomplishing perfect union by the first intention will be materially increased. Mr. Lawrence has tried the plan in many instances, and declares his experience has not found any ill consequences follow, while it has proved that such advantages are undoubtedly the result of it. Mr. Green, of Norwich, however, has doubted some observations which are rather against the practice, and it is especially for him being generally, or even cautiously adopted. After experience it was practised by several military surgeons in the late war, and although they probably did not employ exactly such ligatures as this mode is usually applied, few of them met with any instance of failure from the mistake of the use of suture tied in the wound, with the exception of Mr. Guthrie and one or two other army surgeons of my acquaintance. However, if large ligatures be used, the practice is not fairly tried, or rather the practice is not tried at all: because the great principle on which it consists, is the very small size of the composing the elastic substance left in the wound, where, such ligatures as Mr. Lawrence particularly recommends are employed. *Boissac* and *Rever* have also sometimes adopted the plan of removing the ends of the ligature close to the knot. — See *Parallèle de la Chir. Française avec la Chir. Française*, p. 111. See also *Journal de Chir. Française*, *Hæmorrhage*, and *Ligature*.

Another important improvement in modern medicine, I must not forget the present time rational method of dressing the wound, after the absorption of all vital operations, with light, cooling applications, instead of having for the part a barrier of irritating phlegm and sloughs, and a copious issue made of hot, low, dressed, and other foulness, vesicles, &c. The former the adhesive strips are the better, if they may hold the parts of the wound together. This is all they are intended to do. Whereas, if more than are necessary for this purpose be employed, they do harm by heating the part and covering the wound so entirely as to prevent the issue of the discharge. They also interfere with the progress of the cure, by preventing the escape of the effluvia of suppuration, and some

ferior work, hitherto kept alive by the useful support of credit societies, and patronized by the strict regulations of colleges, they will quickly find (what is truly disastrous) their point left. It is scarcely any principle of misapprehension to be satisfied as the profession, so it only be such as in the result of the kind of education which will furnish, taking in the elements of science and the elements of superior mathematics, and every all-inclusive that would insure the influence of this modern principle, need with external assistance and the hatred of every public-spirited man in the profession.

SURSEPTORY.—A bandage for supporting the wound; a top-dress. Bandages of this kind are very commonly used at the close, and indeed made by the surgeons themselves; therefore a particular description of them is not essential in this work. In cases of lacerated aneurism, rupture, abscess, some particular ruptures, and several affections of the neck, and sometimes even, a sequestrary bandage is of service.

WOUNDS. (From *ana* and *veia*.) A wound is said to be the edges of a wound, by keeping them in contact with each other.

Mr. Adams remarks, that "when a wound is recent, and the parts of it are divided by a sharp instrument, without any further violence, and in such manner that they are made to approach each other, by being directed with the hands, they will, if laid in their correct position, unite by adhesion, and coalesce, like one wound of a true laceration in another." To maintain them in this situation, several sorts of sutures have been invented and formerly practiced, but the progress of them has of late been very much improved. These are chiefly described under the *interrupted*, the *quilled*, the *plaster*, the *plaster*, the *plaster*, and the *plaster*, but the *interrupted* has proved to be almost the only useful one for the quilled suture is never preferable to the interrupted. The *quilled* suture is preferable in some cases to the *plaster* of plaster applied in many different ways to unite the lips of the wound, and the *plaster* is a very useful suture, which is recommended for superficial wounds to prevent the dryness of a scar, and to induce the frequency of union, because it is not so difficult to be removed, in case of a sequestrum and other matter. (*Opera* of *Napier*.) The *quilled* suture is described in speaking of the *quilled* and *quilled*, which also properly belongs to the present subject, forms a distinct article in this dictionary.

Interrupted Suture.—The wound being dressed from all sides of blood, and its lips being brought exactly into contact, the needle, armed with a ligature, is to be inserted from without towards to the bottom, and so on until the wound is closed. Care must be taken to make the puncture far enough from the edge of the wound, but the ligature should not pass through the skin and flesh. This suture, according to Mr. Sharp, may be done in four different ways. The other suture required are only repetitions of the same process. The *quilled* having been all passed, "you are in general to begin by tying three in the middle of the wound; though, if the lips be held exactly together, it will be of great consequence which suture you first." (*Opera*, *capitulum*, *lib. 1*.)

Surgical Suture in general.—The rule of Mr. Adams is a general one, and is based upon the fact of the union of the wound. The common rule is, that one suture is sufficient for every kind of the wound; but that is a very common mistake, and is not properly made, particularly when a wound is very deep, or extensive, or a transverse division of the vessel. As in the case of a laceration, it is necessary to pass the suture in a sufficient distance from the sides of the wound, but the thread should not pass through the skin in a direct line. Although Mr. Sharp says that the necessary distance is general, as there is a four-fifths of an inch, and others give the rule to be always half an inch, and the deepest part of the wound, or the most important part, particularly the last, as subject to numerous exceptions. When a wound is very deep, it would be consequently about, and even, in many instances, to drive the needle through a very thick part of the body. Other wounds of considerable depth, might be, in some places, from wounds of an inch deep, though it is not, which could never be required to pass paper.

The needle for making the interrupted suture will pass with the greatest facility when the edges are carried some way from the surface of a scar, and they should always form a track of sufficient size to allow the ligature, which they drive after them, to pass through the flesh with the greatest ease.

The interrupted suture is very useful in many cases, the interruption between the stitches, and it is the one most frequently employed. Its action is always to be treated and supported, either with the string bandage (see *Bandage*), or with strips of adhesive plaster (see *Plaster*), &c.

Quilled Suture.—As Mr. John Bell has observed, "When the wound was deep, among the muscular flesh, the old purpose imagined, that in large wounds could not be commenced by the common interrupted suture, however deep the muscles might be driven among the flesh, they were, besides, fearful of using the quilled (quilled) suture in deep gashes, but the wound should be made to adhere, especially when a large split open without, forming perhaps a sequestrum or deep collection of matter." They believed, that a deep, somewhat wound, could not be safely healed without a degree of suppuration, while they wished to keep it together at the bottom, they were afraid to close it very exactly at the mouth, but the matter should be collected in the deeper parts of the wound, as from this purpose (says Mr. John Bell) that they used what they called the compound or quilled suture. It is mostly the interrupted suture, with one difference, that the ligatures are not tied over the face of the wound, but over two quills or stiles of plating, or bone, which are laid along the sides of the wound. In performing this suture, we make first two, three, or four stitches either interrupted, rather very deep, and drive all the ligatures being put in, we lay two ligatures along the sides of the wound; then slip two ligatures into the loop of the ligatures on one side, drawing all the ligatures from the other side. (Mr. Bell should rather have said towards the other side), till the temple is fully covered down. Never lay the other bundle, and when the bundle of each ligature over it, and drive it also pretty deep; and that the ligatures, in form of an arch, go deep into the bottom of the wound, and hold it close, while the ligatures or quills keep the middle of the wound, and thus if it, pressed together with moderate pressure, and prevent any strain upon the threads, or any coarse and painful lying across the face of the wound." In a note, Mr. J. Bell says that he has lately corrected the quilled suture, but that Dr. De la Faye, (*Observations on Wounds*), says, it is good for deep penetrable wounds. The quilled suture is now scarcely ever employed; not that it is any advantage, except, perhaps, in some wounds in the body. (*See Principles of Surgery*, vol. 1, p. 26.)

I think the reader will more easily comprehend the manner of making the quilled suture, from the following simple directions. Take an artery needle as is usually intended to be made, run them with a double ligature, or one capable of being easily split into two, introduce the ligatures through the wound, cut off the needles, lay a piece of ligature along one side of the wound, and tie the ends of the ligatures over it. Next draw the other extremities of the ligatures, so as to bring the first piece of ligature into close contact with the flesh; lay the second piece of ligature, going the opposite side of the wound, and tie the other ends of the ligatures over it with sufficient tightness.

Quilled Suture. This has also the form of the interrupted suture. It is as described by introducing the needle that lies one lip of the wound, then within another, then into the other in the same way, and in this manner the whole track of the wound was closed up.

The *quilled* suture has long been rejected by all good surgeons, as it is never to be employed in cases of compound wounds. It was, however, till very lately that this suture was safely abandoned; so Mr. Sharp, and several eminent writers share his view, have introduced it into the practice of the modern and modern. From what has been said in the article *Wounds of the Arm* and *Wounds of the Arm*, the reader will perceive that even in such particular instances the *quilled* suture would not be applicable; so that it is, in every point of view, to be considered as totally disused in every case of surgery which can possibly present itself. What was necessary in making this suture, here many

tender, until a knot was at last formed in it, apparently of a sanguineous nature. Though this was at first as large as a middle finger, and gradually became softer and smaller, yet it did not disappear entirely. Having remained in that size weeks after the accident, the doctor put on a pair of shoes with heels two inches high, and contrived a steel machine to keep the foot in the proper position. This machine, however, he afterwards changed for another, made of the same material as the former. It was not till five months after the accident, that he thought proper to lay aside all assistance, and to put the strength of the tendon to a trial.—(See Moore's *Works*, p. 161.)

Both in a wound and rupture of the tendo Achillis the ancient method of using a salve for keeping the ends of the tendon in contact, is at present quite exploded, and position of the limb in the grand agent by which the cure is now universally accomplished. The following was Desault's method, which, though it was expressly designed to fill all the above-mentioned indications, may not be a more valuable method than what was adopted by Dr. Moore. After the ends of the tendon had been brought into contact, by moderate flexion of the knee and complete extension of the foot, Desault used to fill to the bottom on each side of the tendon, with soft lard and compression. This lard was applied to the limb made as much pressure on these points as on the tendon; and hence this part could not be depressed too much against the surrounding parts. Desault next took a compress, about two inches broad, and long enough to reach from the toes to the middle of the thigh, and placed it under the foot, over the back of the leg and lower part of the thigh. He then began to apply a few circles of a roller, round the end of the foot as far as to the lower extremity of the ischiofemoral compass. After covering the whole foot with the roller, he used to make the bandage describe the figure of 8, passing it under the foot, and across the place where the rupture was supposed; and the method was finished by encircling the limb upwards, with the roller, so far as the upper end of the thigh and last compress.—(See Moore's *Works*, *Chirurgie des Végétations, article de l'Ankylosis*, *Tom. 4*, et *Moore sur la Division du Tendo Achillis, in Œuvres Litt. de Desault par Boyer*, t. 1, p. 283.)

A rupture of the tendon of the extensor digitorum of the leg would require nearly the same kind of treatment as a rupture of the patella. However, in case of rupture of the broken part of the broken tendon should be avoided; the limb should be kept extended, and extended; a bandage might be put round the thigh, and antiseptic treatment be at first adopted. In the course of two or three weeks, the rupture should close, the joint to be very gently moved, without any violent pressure on the part of the patient's knee. When the ends of the rupture are not united as required, the limb is to be kept straight; cold applications are to be used for a few days; and, if necessary, strict antiseptic treatment pursued.

TENT. A roll of lint for dilating openings, &c.

TETTERELLA. (From *tetter*, a pestiferous infection.) A name, or nickname for scabies and other diseases of the skin. A tetther.

TETTERA. (From *tetter*, to bite.) A tetther, or tetther. Also an instrument called a protractor.

TETTERER, HERRASER OF. For an account of many of these appellations, I need refer to dictionaries in this Dictionary; for instance, *Cerveter*, *Petter*, *Herraser*, *Herraser*, *Herraser*, *Herraser*, *Herraser*, &c.

Dr. Desault observes that a disease of the body of the tendon, and in the same manner, it consists, in general, of such an extensive mode in the structure of that organ as produces a granulation by which, fleshy substance, instead of that firm, soft, fibrous matter which it naturally presents. "The disease," says Desault, "is a grey applied to every third coating of the tendon, attended with a total or partial conversion of the part into a fleshy granulation."—(See *Desault's Chirurgie des Végétations*, *part 2*, p. 144.) According to this definition, sarcosis becomes a term indicating of almost general application to marked softness of the tendon, where most of them are attended with inflammation and swelling of the part. "I find," he said, "that the old writers, and a great many of the moderns, call all

diseased inflammations and enlargements of the tendon according to whether the disease is a simple, chronic, tubercle, or cancer, unaccompanied with any symptoms of specific disease or malignancy, or whether it be a stricture, or what is still more difficult and more serious, a truly venereal disease of the organ." Even the fungus herniae of the tendon was, until lately, taken for a cancer.

Thus this vague method of applying the word sarcosis can be attended with no advantage, but on the contrary men have a tendency to destroy all useful classification, in a proposition the truth of which is self-evident. I am well aware that Mr. Pott, and many late writers, set out with an idea that every sarcosis has a propensity to change into cancer, and actual carcinoma, and therefore the latter status are considered by these authors only as stages of the same disease. Indeed, it is well known that a common isolated sarcosis, a simple fleshy enlargement of the tendon, may change into the peculiar malignant disease called sarcoma, or cancer. But yet it is by no means proved, that all the diseases which are comprehended under the name of sarcosis, are accompanied with a risk of their becoming the nature of sarcoma and cancer; for we know that the nature of sarcoma and cancer, is from the first to the last always of one character, and can never change into any other kind of disease. Neither do tubercles, or nodules, swellings of this organ ever undergo such an alteration as deserves the epithets of sarcoma and cancer. In opposition to the belief of Mr. Hunter (see his *Treatise on the Venereal Disease*, p. 20), some surgeons still imagine, that there is really one kind of chronic enlargement of the tendon arising from a venereal cause.—(See *Desault's Chirurgie des Végétations*, *part 2*, p. 144, *Article de l'Ankylosis*, *Tom. 4*, et *Moore sur la Division du Tendo Achillis*, *in Œuvres Litt. de Desault par Boyer*, t. 1, p. 283.) Now this also has usually been called a sarcosis; it was so named by Pott himself; and if there be such a case, no one will suppose that it, or any other form of bone disease, is capable of changing into a true sarcoma or cancerous disease. Perhaps, therefore, it might be more consistent and advantageous to restrict the application of *sarcosis* to an indolent fleshy enlargement of the tendon, unaccompanied with any present or future risk of sarcoma, or any mark of its being the effect of a specific disease; and as well as the case extends to other diseases, the name should correspond with the particular nature of the disease.

We need not here enter into a strict account of the various sarcosities, diseases, in which the tendon is subject. For they have no possibility in them, except what depends upon their situation; and the general characters of the different species of sarcosis will be considered in a future article.—(See *Tetter*.) The tendon is especially liable to three kinds of sarcosis, which have been named by Mr. Abernethy, the cancerous sarcosis, the tubercle, and the swelling. The cancerous sarcosis is called soft cancer of the tendon. It is described in this work under the name of *Fungus Herniae*. Sometimes the tendon is converted into a fleshy granulation mass. It is increased in size, and, when mature, a whitish or yellowish granulated matter is discovered, mixed with pus. This granulation is attended with so much pain and tenderness as a venereal disease of the tendon; nor does it produce any tolerable state of the limb.

As Dr. Baile observes, the swelling when first discovered is a hard mass of a pearly white colour, and generally increased with inflammation. Sometimes there is only a small mass, which is called with a cancerous fluid.—(See *Desault's Chirurgie des Végétations*, *part 2*, p. 144, et *Moore sur la Division du Tendo Achillis*, *in Œuvres Litt. de Desault par Boyer*, t. 1, p. 283.) This is the true *sarcosis* of the tendon, which is attended with great hardness, severe pain, and a swelling along the spine of the tendon to the joint, and an enlarged artery. In general, the tendon becomes in pain. To see Mr. Pott's words, see the history of the cancerous sarcosis in the text; but, passing it over, the swelling of the tendon, which swells the muscle, and is called a large, soft, striated, fleshy enlargement, with thin veins, or it is called a pearly, granulated, fleshy, and is frequent appearance.—(See *Desault's Chirurgie des Végétations*, *part 2*, p. 144, et *Moore sur la Division du Tendo Achillis*, *in Œuvres Litt. de Desault par Boyer*, t. 1, p. 283.) These latter states of the disease are denominated cancer of the tendon.

Should we hope, the *sarcosis* infection, coming from the venereal system, along the tendon, and even within the tendon itself. In this case, the

ping all cases time after the enlargement of the testicle.

In some unusual cases, the volume of the scrotum is increased with an enlarged testis, which occasionally appears in youth also, and presents the appearance of an enormous scrotum. An example in which the former weighed three lbs has been published by Dr. Tilley.—*See Med. Clin. Trans. vol. 8, p. 73*.—In one case, recorded by Dr. Cheyne, a swelling of this kind was as large as an child's head. On dissection of the parts, the testicle and epididymus were found to be quite free from disease. The largest concealed swelling from an enlargement of the cellular membrane, which immediately covers the external surface of the vaginal coat. Two curious diseases were observed in women's ovaries, and several instances of it were met with in Eggs by Harris Laney.—*See Med. de Chén. Jekere, t. 2, p. 116, et seq.* Mr. de Velde lately at Dublin, observed one in a case in which he had removed from the scrotum a large mass of fat, containing the testes and even a hydrocele.

The operation of castration is the most efficacious of relieving the patient from varicose. This measure, however, is not practically applicable, nor is it always necessary; for sometimes the enlargement of the testicle subsides of itself, displaced by the absorption and removal of internal morbidities and external appearances. The hope of accomplishing this desirable effect may be occasionally entertained, when the swelling is not very large, when it has not existed a considerable time, and when it is not attended with very great inconvenience. Experience has proved, that some kinds of varicose have yielded to the treatment of tincture (*Morrey, Fragile, and Rose, in Chemical Dispensary*); in a dissection Harris gives (*Hippocras del. Med. Acad. Berol. Clin. Berol. t. 7, p. 504*); in French and Latin (*Waller*), in German (*Le Dyon, D. Hoff, Malacodon, Delphic*), in the external use of the *lycopodium*, *atractyl*, and *compounded mercurial ointment*, in powder containing (*Fleming, d. Med. Trans. vol. 6, p. 10*); in a lotion made of a strong decoction of haddock (*Waller*); in the application of mercury, in repeated employment of iodine, and the application of cold, &c. It also sometimes happens particularly in females, that the internal and external use of the preparation of iodine are found to be attended with strongly marked efficacy, in cases where the affection of the testis, especially those reputed to be scirrhus. Many facts of this kind have been reported to me by my patients, myself, similar ones I have witnessed myself, and they are well worthy of being remembered in practice.—(*See below*). The operation of all these means may be advantageously preceded by the external use of a bag made, the coverings as much as possible, of a horizontal position, and attention to a suitable low diet.

Mr. Port believed, that the man who has the varicose is to be affected with a varicose, but very little change of getting rid of the disease by any plan, except castration; and all the time the operation is deferred he carries about him a pair, not only useless, but burdensome, and which is every day liable to become worse and unfit for such an operation. Now, although there is a great deal of truth in this opinion, yet, I conceive, it is rather exaggerated, and that it would tend to diminish the practice of castration to an extent beyond all necessity. Particularly since with Mr. Port, that there never was a varicose case, where the enlargement of the testicle had been destroyed by disease, or where the disease had suffered so much as to render it incapable of the office for which it is destined. But such some reason always be known in respect to, natural examination; and were a surgeon to be directed to the body every testicle which he finds affected with indurated swelling and induration, and not readily reducible, he would immediately apply such order as to the above plan of treatment, which would be perfectly cured. That there are some cases of enlargement of the testis, which may be viewed, as a mark, of which experience must have observed the generality of surgery.

The scirrhus testicularis, and several other swellings of this organ, which are very imperfectly understood, may sometimes be benefited, and even entirely cured, just like some analogous affections of the breast. What is termed the *scirrhus testicularis* (Mr. Port always always gives way to a mercantile course, properly con-

ducted. The diagnosis of this case, it must be confessed, is not very clearly explained by surgical writers, nor was it really acknowledged by Mr. Hunter. According to Mr. Port, it is indeed a variety of scirrhus; and he does not therefore ever to have seen an instance in which it was not either immediately preceded or accompanied by some other appearance plainly varicose. He adds, that it has marked the irregularity of the point of varicose. But the question whether the case is really varicose or not, is far less interesting than the question whether there are not many varicose which may be diminished and cured by surgery. The affirmative cannot be questioned. I have seen many such cases myself, and they are frequently recorded on record. A statement of several has been lately published by Robertson.—(*See Næphrologia Chirurgica, t. 2, p. 386 of top. vol. 4*). The authority of Hippocrates is also on the same side.—(*Præf. Epidemiorum de Morbis Hippocratis t. 3, p. 364*).

Indeed, this last writer comments, that many varicose swellings, and even of the testicle are so much alike in their progress, that the difference of their situation should always be at once detected by the punctation. Hence, although I am an advocate for the early performance of castration in cases of varicose, when there is reason to suppose the disease to be advanced, that the organization of the testicle is totally destroyed, or where internal and external remedies have been used a certain time, as I say; yet these sentiments do not induce me to recommend the operation in other affections, in which the disease is quite recent, and no plan of treatment previous to the operation is tried. I have already examined various cases of scirrhus, which have been proved by experience to be sometimes capable of being cured. The disease of the testis, which is usually called the *scirrhus testicularis*, like other forms of scirrhus often goes well spontaneously after a certain time, and it may frequently be considerably benefited by administering internally the correct medicines, and such doses of the substance of mercury, bromine of mercury, or positions of surgery, being applied to the scirrhus. The good effects of iodine in such cases, I have already noticed. Several other incident enlargements of the testis yield to iodine with comparatively momentary advantage to the scirrhus. The late Mr. Robinson thought that some scirrhus might be relieved by dressing with leeches, a supposed morbid irritability of the urethra, with which he thought it him to connect the origin of the complaint.—(*See Pract. Obs. on Scirrhus, &c.*) The history of this supposition, for a time, attracted considerable notice; but the interest which it once enjoyed has now died away, a sufficient proof to be made, that the practice mentioned was not of much value.

From the preceding observations, it may be inferred that all disease enlargements of the testis are not curable; but that we ought at the same time to be duly impressed with the expediency of not waiting too much time in the trial of means which we are to be depended upon, and which, if continued unnecessarily long, might show the disease to advance too far to be capable of being afterwards effectually extirpated. According to Mr. Port, the circumstances in which the operation of castration is advisable or not are of two kinds, and relate first to the general habit of the patient, and the disorders and indispositions of some of the viscera, or to the state of the testicle and spermatic cord.

A pale, sallow complexion, in those who used to look otherwise; a weak constitution, and almost apoplexy and death, without any more disorder; a fever of the testis kind; and frequent pain in the back and loins; are, in those who are afflicted with a scirrhus testicularis, such circumstances as would induce a suspicion of some latent morbidity in some of the viscera, in which case, as Mr. Port truly observes, no cure from the mere removal of the testis is not to be expected. They whose constitutions are spoiled by intemperate practices in their being attacked with this disease, who have hard liver, and aqueous humors, he says, are not proper subjects for such an operation. Hard recovery within the abdomen, in the regions of the liver, spleen, kidneys, or rectum, indicating a diseased state of the said viscera, are very material objections to the removal of the testis and spermatic cord. In short, whenever there are manifest

uniformly met with in every case of rapid or violent death. Besides the rigidity and increased sensibility of these parts, Baron Larrey has likewise stated that the pharynx and oesophagus were contracted and refused either food or liquid nourishment. He also found sanguine hæmorrhages in the bowels of the several patients who died.—(See *Mem. de Chir. Militaire*, t. 2, p. 462.) This, however, is evidently an accidental complication, and not a disease. In several cases, Dr. M'Arthur found the intestines much inflamed; and in two of them a yellow watery fluid, of a purulent effluvia, pervaded their mucous surface; but whether the inflammation of the pharynx or only a consequence of the pressure of the abridged muscles, which contract in violence in this disease, he is unable to decide.—(See *Brit. Chir. Trans.* vol. 7, p. 65; and *Baron's Synopses*, &c. *Tetanus*.)

Dr. Louis Chambers, of Charleston, South Carolina, states that when the disease forms very quickly, and reaches the uniformly present with the whole train of its characteristic symptoms in a few hours, the disease is pronounced by the rigidity of the attack, and that the patients then succumb generally in twenty-four, thirty-six, or forty-eight hours, and very rarely survive the third day. But when the disease is somewhat less violent in the attack, he is unable to decide.—(See *Brit. Chir. Trans.* vol. 7, p. 65; and *Baron's Synopses*, &c. *Tetanus*.)

From the valuable report of Dr. James Magrath, it appears that several hundred cases of tetanus occurred in our army during the five campaigns in Spain and Portugal. The disease was observed in some on several occasions after the receipt of the local injury, but it terminated on the second, third, and fourth days, and even at one of our detachments where it continued, though it was usually the post-mortem beyond the eighth.

—(See *Brit. Chir. Trans.* vol. 8, p. 325.) I had a patient, however, who expired in the military hospital at Falmouth six weeks after running between, before he died. This happened in the year 1814, soon after the capture of Bayona by Buonaparte, when the patient had been wounded, and a medical suspicion of the truth.

Although tetanus is a disease which has been observed in almost all parts of the world, experience proves that it is especially so much the greatest in warm climates, and especially in the low countries of those climates. The disease is common in many situations and countries bordering upon the sea, and in places situated very dry, elevated, and at a distance from the sea. Every class of individuals is exposed to the attack; but within a few days after their birth, and children and persons are said to be often affected with older persons, or they in the youthful period of life. The young are more frequently seized than the female; and the female and children more frequently than the male.

According to Dr. Osler and other medical writers, the causes of tetanus are cold and moisture, applied to the body while it is very warm, and especially the sudden transition of heat and cold. Of the disease is produced by morbid humors, or other injuries. When wounds, however, tetanus is probably more often caused, which it is not directly known.

Baron Larrey observed that post-mortem wounds in the course of the service and the troops of the army often produced tetanus in the climate of Egypt, particularly when the patient or temperature passed from one climate to the other, in damp situations, and in those which were subject to the heat of the sun. What he observed and noticed subsequently was the most subject to the disorder, the extent of which was found to be almost always fatal.—(See *Mem. de Chir.* &c. *Tetanus*.)

Through tetanus is regarded to proceed of course from wounds of the extremities, then from wounds of the head, neck, and neck. Sometimes it is regarded as the symptom of the disorder, as in the tetanus, mentioned by the late Professor Boissier of Edinburgh; but in general it does not arise in all wounds. It is observed, sometimes, and the wound is merely a slightly lacerated, and free from all pain and violence. Wounds of every description that give rise to tetanus, and in which tetanus has been fatal in the post-mortem. Thus, in Egypt, Larrey had tetanus, which terminated from the laceration of the muscles of the hand in one of the soldiers of the army.—(See *Mem. de Chir. Militaire*, t. 2, p. 254.) In colder climates tetanus is observed in lacerated wounds, even when cold, moist, or lacerated wounds; or

wounds of the glistered plant, with laceration of the tendons and ligaments, contused fractures or dislocations, deep lacerations in the sole of the foot, and especially lacerations of the tendons of the fingers and toes. A partial division of a nerve has been supposed as a cause; but as some nerves must be imperfectly cut through in almost every wound, and yet tetanus does not arise, the reality of this cause is doubtful. Besides, if it were true, the cure would be easily effected, by making the division of the nerve complete, which experience contradicts. Baron Larrey, however, has observed a fact which favors the opinion, and it still presents itself; and a case in which the laceration of the tendons of the foot to the thumb was found only from strength, and as extremely inflamed and lacerated, has been related by Dr. Larrey.—(See *Mem. de Chir. Militaire*, t. 2, p. 254.) The inclusion of the nerves in the wound applied to tetanus is another alleged cause of tetanus; and as this fact is very common, and tetanus rather rare in this country, while it may follow all sorts of wounds, whether from perforation or rupture, the accuracy of this opinion may also be doubted. In support of it, however, there are some cases and observations adduced by Larrey, which will be given in the sequel of this article.—(See t. 2, p. 254, &c. *Mem. de Chir. Militaire*.) At the same time I do not seem to find that the nerves are not sometimes in tetanus, as if the practice is not now a second time. Amputation and cauterization are the only great surgical operations in which I have seen tetanus succeed; though it may follow the amputation of the limb on some occasions.—In Dr. Boissier's Hospital, it was followed the operation of removing the foot.

In warm countries, tetanus is an ordinary consequence of all kinds of wounds.

There cannot be a doubt that differences of climate induce considerable differences in the nature and danger of tetanus. Larrey found that in Egypt, the disease was more intense, and more violent, sometimes to hydrophobia than in the other climate of Germany. In both these countries he remarked that, when the wounds causing tetanus injured nerves, situated on the first part of the body, tetanus was more common; that if the posterior nerves were lacerated, tetanus followed; and that when the wound extended from the first part of the body, tetanus was less common, though it is likely as to require equally both descriptions of nerves, complete tetanus ensued. He observed, also, that the disease commonly arose from wounds when the climate and temperature passed from one extreme to another. Regarding to the cold, damp, continued air he found particularly conducive to it.—(See *Mem. de Chir. Militaire*, t. 2, p. 254.)

In the low countries in Spain and Portugal, according to the report of Dr. James Magrath, tetanus occurred in every description and in every kind of wounds, from the situation to the most elevated; it followed the healthy and the sloughing, the fetid and the lacerated; the most simple and the most complicated. It occurred at uncertain periods; but it was remarked that, if it did not commence within twenty-two days from the date of the wound, the patient was safe.—(See *Brit. Chir. Trans.* vol. 8, p. 325.) In Egypt, as we learn from Larrey, the latest period of the commencement of tetanus after a wound, was from the fifth to the eighth day.—(See *Mem. de Chir. Militaire*, t. 2, p. 254.)

It is observed by Dr. Boissier, that at the same time of tetanus is an inflexible fatal, it is of the greatest importance to attend to whatever may tend to destroying the disease early, or to reducing it off. Boissier states that it is wounds producing convulsions and tetanus, a presymptomatic of the whole during which often gradually passed before any affection of the lower jaw; and we should naturally give our attention to any affection of this kind as presymptomatic or tetanus, particularly of the tendons of the hand, forearm, back, &c. Some physicians maintain that tetanus may often be derived from the laceration of pain, irritation, excitement, nervous tenderness, pain and difficulty in deglutition, or in turning the head, or in partial rigidity of some of the voluntary muscles; pain at the cerebral centre; a suppurative or empyema of the discharge, &c. which such the slower approach of the disease. Larrey adds several varieties of tetanus, in which the

Wound was either dry or afforded only a scanty serum exudation, and where the symptoms were relieved on suppuration being re-established, and Dr. Reed (*Eccl. Med. and Surgical Journal* for July, 1854), remarks, that on removing the dressing the wound was covered with a darkish crusty-looking matter, and that he had seen this change the occurrence of pressure in two other instances. A vapor of the exudates has previously been observed to protrude at will in necessary the dressing, and Boyer, in discussing exanthema in obstinate cutaneous eruptions, makes the following remark:—(Treatise Med. Chir. &c. 1, p. 255.) Mr. Abernethy also informs us, that in such cases we must be regarded into the state of the vessels, the exanthema were not the seeds, and he proposes as a question, is investigating the cause, what is the state of the blood, is between the influence of the injury and the appearance of this morbid exanthema?—(Abernethy's Surgery, Works, vol. 3, p. 304.) Dr. Ferri thinks the tendency of the circulation a useful criterion of the danger of the disease, and observes, that if the pulse be not above 100 to 110, by the fourth or fifth day the patient almost always recovers. But even if it be upwards of 140, the disease usually proves fatal, and nevertheless a few instances of recovery where the pulse continues to 120 on the first day.—Baron Lundy remarks, that when the perspiration which so often attends the disease is symptomatic, it begins upon the head and extremities; but that when it is diaphoretic, it comes over the chest and the abdomen.—(Galenus Chir. Medicae, l. 1, p. 235.) It is much to be feared, however, that in such cases perspiration does very faintly, with out sufficient relief (*Revue Chirurgical*, art. Dittmar

It has proved to be exceedingly more consistent of tetanus, a subject of infinite difficulty, because the disease frequently baffles every mode of practice, and, in certain instances, goes well under the employment of the very same remedies which *seemingly* fail in other similar cases of the disorder. Every plan has, certainly, been tried, and every plan has still more frequently succeeded. The great difficulty, therefore, is to ascertain, among numerous dissimilar accidents, what position is held on the whole to be attended with the least ill-success? For in the present state of our knowledge, the most judicious practitioners will not differ far from the supposition, that any essential remedy for tetanus has yet been discovered. As, however, acute tetanus was regarded by Hippocrates and the ancients as curably fatal, and as open not always proven as modern things, it seems allowable to conclude that the occurrence of such now happens is due to merited improvements in practice. This reflection would lead us not to give either subject as hopeless; but to redouble our exertions for the discovery of a more successful method of treatment, and, if possible, of some new medicine, possessing more specific powers over the disorder.

As it is justly observed by a well-informed writer, when we reflect upon the obscurity which involves both the *causæ ætiologicæ* and the *proximate causæ* of nervous affections, we need not wonder that the practice in these disorders should still be entirely empirical. The indication of cure, which is generally applicable to all diseases, namely, the removal of the exciting causes, has but little place in a nervous condition, which is the consequence of causes that in general have ceased to act, or which it is not in our power either to remove or control. In those cases, where we could suppose local irritation to be still operating, the most effectual method of counteracting its effects on the system would obviously be to interrupt all communication between the seat of the irritation and the nervous system. If, however, the disease has already established itself, and the system is again healthy, even so, it does not appear that this could succeed in arresting the course of the disorder. Experience has but too fully proved, that the apparatus of the limbs, from the injury of which the spasms have arisen, will very seldom permit even a mitigation of the spasm, and, if permitted after a certain period from their first appearance.—*Rich's Dyspepsia, etc.* *Spasms*—Barro Laffrey has been the greatest modern advocate for the performance of operations in cases where, in his opinion, depends upon a wound of the externalities; but the facts which he has adduced in its favour are not numerous, and he finds his representation of the necessity chiefly to derive vanity, and exclude it is a

others, except on the very first occasion of the imp-

The usually unexpected and rather serious Larry, obtained by the strength of his jaw, took, in the process of an—seemed to Chris—telling, he was to prepare to—some part of the exhibition, it would be the—signify the danger that immediately he was—brought himself, rather than expect him to—pieces of nature, and from very accurate results, a case which is seldom happens?

"If present, it is elastic," he is somewhat over-
stating, as it may be *less* in every point of the
center, provided a choice be made of the line
there in the interpretation of the structure. The
upper middle arch, however as well as some of the
lower, the diameter were widened, and the muscle to be
raised were strongly contracted, and, in a little
obscured in the angle of Arch in a rather early
action with rotation, in interpretation of a possible
rotation of the left elbow. — (*Ann. of the Acad.*
1, 3, 3, 202.)

Many old, faded, yet legible, is a few details of acute interests. In the case last cited the symptoms were already considerably advanced when the experiment of reanimating the man was made, and, says he, the operations were followed by considerable success. The symptoms returned, however, a few times afterward, and proved fatal on the third day. In another case, also, the gentleman opposed the treatment, though some friends said he was. The action is described as having stopped at the throat, and, at that point, by exertion [?] the pressure was passed twenty bones in perfect ease, but, I regret to say, the sharp cold air, the disagreeable heat, and other circumstances—(See *Mem. de Chir. Militaire*, t. 1, p. 232-233)—led to a loss of acute interest, where Mr. Bland suggested the worsted band, the symptoms remained following day; yet the case ended fairly, and is a question, whether the degree of temporary shock which was obtained did not prove fatal to the fracture. Tried in conjunction with the operation—(See *Art. Med. and Surg. Journ.*, N. Y., 79, p. 232).

Lately, wounds soon close in Great Britain, and the consequences of disease are lessened, and especially for the relief of the disease in the chest. From the late knowledge obtained on this subject, it is now possible to relieve and even to cure the disease off all communication between the cavity of the wounded part and the atmosphere by a suitable instrument.

In this place I think it right to remind the reader, although Harper Lacey once or twice admitted when some tenants had suggested otherwise, he did not subscribe the principle, and he certainly neither in sections of acquisition in Chicago, or in some isolated cases of tenements, and to a few farmers in 1893. In playgrounds and in districts, without which, as a representative of the class, would possibly require no operation.—(See Mem. of Chas. M. L. B.) The report of Sir James Macpherson, lately confirmed the statement of Lacey, namely, that the tenants were a little afraid in the night and fully bowed down by that superstition falls in the same kind of way. In the latter of Toronto, this operation was somewhat tried, but without success. The French are usually to have had an immense number of soldiers, but because after the battle of Verdun, when, it is well known, that the practice of acquisition was hardly tried.—(See Mem. Chas. Travers, vol. 1, p. 18.) We have seen, however, that according to the reports of Lacey, the English might have only performed the operation in eleven cases, which was the last, for instance, or if in other instances, may be the very first acquisition of the acquisition. Perhaps while not abandoning the greater degree of that applying Lacey's statement, there is nothing in it deserving any better, than attention to the report, in cases of extreme tenants, who seem to be actively adopted. The average effect of the operation, however, and the occasional possibility of a return to the conclusion by a single year, will be a considerable immediate advantage to the tenants.

Since Gertrude, widow of the late Sir Arthur Conan Doyle, has published his records of spending the plot of *Dragnet* in class of the

and they tend to confirm the opinion which I have always given upon the subject. In one case of tetanus, from a compound fracture just above the ankle, the operation seemed to postpone the fatal event. In another case, the leg was amputated without any good, and a third case is referred to, in which the operation also failed in curing the puerility. In chronic tetanus, amputation is reported by Sir Astley Cooper as ineffectual, as the paralytic action returns without this proceeding. The medicine which has succeeded in this puerility must be useful in such cases, as the substance of mercury joined with opium—(*Surgical Essays*, part 2, p. 180.)

Dr. Abernethy, in his lectures, also disapproved of amputating any important part of the body with the view of relieving tetanus, unless the injury exposed the possibility of its being prevented by amputation; however, that he has seen tetanus mitigated by the practice, though the patients ultimately fell victims to the disease.

On the subject of making incisions for the purpose of separating the disease of the wounded part from the system, Larrey states, that they should be performed before inflammation has commenced; for if this has reached progress they would be useless and even dangerous. They should consequently, as much as possible, be at the remote extremities and superficial parts. As he considered all incisions very painful, as exacerbating the symptoms of tetanus, instances of which he has observed. The Surgeon has resorted more to covering parts of the body with lint, arising from completely dividing the track of the injured nerve. In one instance tetanic symptoms followed an injury of the sympathetic nerve, but were immediately stopped by dividing some of the fibres of the sympathetic cord, and the tetanus and convulsions, deep to the bone.

On the principle of destroying the parts which are the seat of the local irritation, Larrey also frequently applied the actual and potential caustery to the wound. The application of caustics, says he, may be performed with advantage on the first attack of the symptoms, the same concept being directed to its striking the incision. Bleeding, leeches, and the usual topical remedies and doodynes, may follow these operations. Though in general they have little effect—(*Mém. de Larrey*, *Annuaire*, vol. 2, p. 248.) In the third volume of this interesting work, p. 271, &c. are several cases in which the caustic was employed with success. We could not exclude, however, that such dependence ought to be placed in the use of the caustic, since Larrey observes, in another place, "The actual and actual caustic, recommended by the Father of Medicine, have been equally unavailing. The actual was employed at Jaffa upon three wounded men; the disease nevertheless followed its usual course, and destroyed finally."

"I have used a striking instance of the inefficiency of the second method, in a case of opisthotonos."—(*J. J.*, p. 258.) This author also addresses some cases which tend to support the opinion, that tetanus occasionally proceeds from the infection of a large nerve in the ligature applied to an artery. The use of French Brandy as a direct of tetanus consequent to amputation, and upon extending the stump, the median nerve was found included in the ligature with the artery, and as extremely swollen, and swollen—(*Mém. de Larrey*, *Annuaire*, t. 3, p. 267.) In another case, Larrey suspected the tetanic disease to proceed from a putrid branch of the trunk nerve being cut together with the spinal artery, and he cut the ligature; but the relief was only partial and temporary. The patient was therefore applied deeply to the whole surface of the stump. A violent convulsion took place a few hours afterwards, and the patient recovered. A diaphoretic mixture, with camphor and opium, was also exhibited—(*J. J.*, p. 267.)

Among other local means for the relief of tetanus, we might as well omit the employment of Muriatic acid as much as possible in the wound, or their application, or that of the stimulus of camphor, or the liquid itself. Almost all modern writers have observed, that tetanus is interrupted by its intermixture, and in its progress with an intermission of total cessation of spasm in the wound. Hence, the indication to excite this pause again, by the means which I have specified. Clearly seems to have adapted both plans; but he particularly applied the element of caustic.

due to the wound itself is an early stage of the spasm, and in cases where there not only tend a suppuration of the discharge, but where he suspected the nerves of the wounded part had suffered from exposure in the cold damp air, or the detachment of the muscle. The facts in favour of these local means, the reader must refer to the first and second volumes of the *Mémoires de Chirurgie Militaire*.

It appears also from Larrey's experience in Egypt, that patients, made of the waters of Salsola, and applied to the wounds of persons labouring under tetanus, are followed by no advantageous effect. The alkalies also proved of no service—(*J. J.*, p. 261.)

I shall conclude these remarks on what may be offered the local treatment of tetanus, with mentioning, that the celebrated Dr. Rush recommended the wound to be dressed and dressed with oil of turpentine (*see Treatise of the American Phlog. Society*, vol. 2); and that some of our naval surgeons have used tincture of opium as a dressing.

A great degree of obscurity prevails respecting the most eligible period for constitutional plans of treating tetanus, and I am afraid, it will be perceived, that our internal remedies cannot be more depended upon than the local means already described. This opinion is fully confirmed by observing in the foregoing fact, referred to by James Macgregor, that out of several hundreds of cases which occurred in the British army during the late campaigns in Spain and Portugal, there were very few which terminated successfully, or in which the remedies, however varied, seemed to have any beneficial influence after the disease had reached a moderate progress—(*Med. Chir. Trans.*, vol. 6, p. 448.) The possibility of doing much good by internal medicine is also sometimes totally prevented by the inability of swallowing, which afflicts the patient. In short, the present state of our knowledge, respecting tetanus, will not allow us to indulge much hopes of cure from any means yet discovered, except in the chronic form of the complaint; the resources of success in the treatment of acute tetanus being by no means numerous, and not the result of any determinate plan of treatment.

Of all medicines, again, is that which has raised the greatest expectations, and been the most extensively tried in cases of tetanus. Indeed, there cannot be a doubt that, in many cases, with more it is compared to effect a cure. But for this purpose, it is absolutely necessary that it be in larger doses than the current quantities of the symptoms; that it be given in very large doses; and that the doses be repeated at short intervals, so that the system be kept constantly under the influence of the remedy. It is, indeed, astonishing how the system, when subjected under a tetanic disease, will mask the operation of this and other remedies, which, in its ordinary state, would have been more than sufficient to overpower and destroy it. Patients with tetanus will bear, with impunity, quantities of opium which at any other time would have been certainly fatal. Instances are upon record of five, six, and even twenty grains, being taken every two or three hours, for many days, without any extraordinary narcotic effects being produced upon consciousness. It is perhaps advisable, however, to begin with comparatively moderate doses, such as half or one drop of the tincture of opium, which may be repeated at intervals of three or four hours, and increased at each repetition until some sensible effect is produced on the system. It seems requisite to augment the dose rapidly, as the disease presses upon us every hour, and so that we may be lost when there is yet a chance of conquering its fury. The approaching closure of the jaw, and difficulty of deglutition, which may prevent us thus readily it is hardly possible to introduce medicines into the stomach, are notional motives for pushing our remedies before such obstacles arise—(*Précis de Médecine*, art. *Tétanos*.) I once supposed it possible to overcome this impediment by introducing a flexible catheter down the oesophagus from side of the nostril; but this attempt to do this always terminated in a violent prostration of spirits, attended with such a sense of suffocation that it could be endured. The experience of my friend, the late Mr. Crichton, of Bath; and that of Baron Larrey, have fully proved, that no sedatives can be derived, in these circumstances, from the use of flexible tubes—(*see Mémoires de Larrey*, *Annuaire*, t. 1, p. 257.) Sometimes,

however, the obstacle to the administration of medicines arising from the closure of the jaw, is prevented by loss of some of the incisor teeth, and, in a few instances, Baron Larrey adopted the plan of extracting two of them. This would be tedious, however, were deglutition be totally hindered, as happened in two instances recorded by the latter eminent surgeon.—(*Op. cit.* t. 5, p. 331.) Clysters are the only remedia which the spasm of the Glæva cannot be overcome. In this way, as much as a bucket of the extract of opium has been introduced into the bowels at one dose. Opium friction upon the jaws, throat, and other parts of the body, have been practised. Opiate plaisters have also been applied to the diaphragm muscles, and behind the ears. This external use of opium, however, can only be regarded as a feeble and probably useless method.

A curious fact, noticed by Mr. Anstey in his lectures, seems to offer some explanation of the little effect of some of the most powerful medicines on the irritation in tetanus; on opening the stomach of a patient it was found that he had died of tetanus, after taking three doses of opium, many drachms of this substance were found undissolved in the stomach. Whether opium will have more power over tetanus than the common preparations of opium, must be decided by farther experiment; but I confess that my own expectations or so desirable a circumstance are not very sanguine.

As the convulsions always produced by tetanus is rendered still more nervous by spasm, laxative medicines and opium should constantly accompany its employment. The weakness of the artery physicians, as we learn from the report of Sir James Macgregor, is highly in favour of a rigid pericranium: is the use of blisters given in adequate doses to produce daily a half effect. Dr. Ferrius notes, that a solution of sulphate of magnesia, in infusion of scum was found to be more better than any other purgative; and it was daily given, in a sufficient quantity to prevent a copious evacuation, which was always dark coloured and highly offensive; and to this practice he chiefly attributes, in one severe case, the removal of the disease.—(*Med. Clin. Trans.* vol. 6, p. 452.)

A spasmodic rigidity of the muscles being the most prominent symptom of tetanus, it was treated for some time by the effects of some other muscular medicine besides opium; and those which have been particularly the subject of experiment are camomile, ether, the common mustard, bark, castor oil, and lastly the digitalis. In many cases, opium and camomile have been exhibited together. Indeed, Larrey asserts, that of all the medicines hitherto proposed by skillful practitioners, the extract of opium combined with camomile, and the tincture of potassium, in a small quantity of the alcohol stramonium, and given in doses more or less strong, produces the most favourable effects, since patients, who have no attention to other fluids, take with pleasure this mixture, the action of which upon the system is attended by necessity, and Quina, under the circumstances which have been specified.—(*See, Med. Clin. Trans.* t. 1, p. 22.) In the same work, several cases are detailed which were benefited by such treatment.

Although some practitioners have thought that they saw good effects result from bark, yet the majority, who have made trial of both this and camomile in cases of tetanus, have found no reason to recommend these remedies. One hundred and fifty grains of bark have been given in the space of twelve hours, to a young girl, without effect, not assisted with an increased quantity, but on contrary effect on the disorder was produced.

We learn also from Sir James Macgregor, that ether, camomile, castor, and other antispasmodics, as likewise the alkalies, were tried by our military surgeons in Spain, and found unsuccessful.—(*Abdoen-Clin. Trans.* vol. 6, p. 453.)

From the same authority we find, that digitalis, in large doses, was used in several cases in the Peninsula; and that it, with several other medicines administered, failed in almost every case of acute tetanus which occurred.—(*P. 44*). In one case the pre-mentioned failed in the last, and the patient was recovered five days afterwards.—(*P. 45*). I am not acquainted with the particulars of any case in which belladonna has been given, but whether it be a remedy worthy of farther trial.

Analogy has also led to the employment of the warm bath, as a plan which seemed to promise great benefit, by producing a relaxation of the contracted muscles. But notwithstanding this method has succeeded in some instances, is seldom more than palliative, particularly when the practitioner has been connected with the Government, is generally false, and often has more than succeeded. This may perhaps be, in some cases, attributable to the circumstances and amount which is poured into the muscular system in order to produce the bath; for it is very well known, that every exertion on the part of the patient is very apt to excite violent paroxysms of spasm. The writer of the article Tetanus, in the *Encyclopædie Médecine* mentions his having seen the warm bath in five or six or three cases in which it was expected to produce good. Through misapprehension there is committed the mind of the plan it would be difficult to come to their accuracy, nor have whilst generally more on the adoption has ever been followed by successful results. The warm bath was tried in Spain and used to produce only momentary relief.—(*Med. Clin. Trans.* vol. 6, p. 457.) Dr. Henry, who has used a long while in the warm climate of Vienna, writes, tetanus is very common, disappears of the season of treatment. He observes, that although the warm water bath may appear to be very mild, and pleasant to be used, he always found it more not serviceable than expected with an occasional exception, and he also mentions, that in his hospital many patients die the very instant when they are out of the bath, notwithstanding they had no less as it were this remedy administered, the temperature of the water being however not higher than in warm bath, the thermometer.—(*See, Mémoires de la Soc. et Mémoires de Médecine*.)

Dr. Hays also mentions similar fact of a patient dying the instant he was taken out of the warm bath.

Hyperæsthesia was an obstacle for the application of cold water to tetanic patients. The only means of the cold water was first particularly suggested by Dr. Goussier, in the *Arch. Méd. Clin.* and secondly, and the plan has subsequently received the sanction of Dr. Wright, Dr. Corrie of Liverpool, and others. As to the procedure which have been employed in cases of tetanus, the cold bath is expressed by some authors as that which has been attended with the greatest success. Dr. Wright published in the *Arch. Méd. Clin.* vol. 6, a paper containing a narrative of the last cases of this method, which were all successful. The plan would be performed throughout the Week before 2 o'clock in the morning, the patient in cold water, and in case of the way, when at hand, or poured in the water, or else in throwing from a certain height into a tub of cold water over his body. After this he was to be very carefully dried with a cloth, and put to bed, where he should pay no further account with disease, and most theory of things were to be done. The symptoms usually seen in tetanus in a human degree, but the relief which this method affords is not of long duration, and it is necessary to repeat the water immersion at the end of three or four hours. They are to be repeated in this manner till the intervals of freedom over the attacks of the disorder increase in length. This desirable end, it is said, generally were obtained, and ends in a relief. The arms and legs were sometimes collapsed with the foregoing system, and seemed to contribute to the production of the good effect. Dr. Wright concluded the account with the following remark, and to this you may refer, by the *Encyclopædie de Médecine*.—I am persuaded, that opium and the cold bath with some slight relaxation for tetanus and such like diseases, of which the system discharges the morbidities, and given more from the violent spasm, the cold bath would still have a wonderful tonic effect on the system in this and other cases. Perhaps this bath, given with more would come the more sure certain. But we cannot have failed in many cases, by using opium alone in large doses, or when probably it were, with the warm bath instead of the cold bath? And lastly we are disposed to suspect, that the increased doses of opium which were administered when the water bath failed, may have proved beneficial.—(*Vol. 6, p. 459*.)

Our next subject now we come to Spain, we said to have found the cold bath more than others.—(*Med. Clin. Trans.* vol. 6, p. 454.) and lastly I beg to remark

particularly, that the plan seems to present no hope of benefit in cases of tetanus from wounds, however strong the evidence is of its utility in other examples of the disease. This was the opinion of Hippocrates, and, in modern times, that of Dr. Cullen, Calaneo, &c. "Dantoni's saline baths before corpora in apoplexia in tetano a calidum interius vires prodere, in tetano a causa externa admodum effectum prout."—*Agrippæ Chirurgia Medica*, part 1, p. 109, 110, 111, 112. On the subject of cold effusions and bathing, there are on record two cases, which are curious. One is related by Hæm. Læmy. It was an instance of tetanus from a gunshot wound. The cold bath was used. The first two trials gave the patient extreme pain, and no improvement followed. The sight of the bath the next time filled him with an invincible dread of the water, into which he refused to be put. He was removed, however, to the bath, and remained. The tetanic stiffness was immediately increased and death followed. It became necessary to remove him directly from the bath, and put him to bed. Deglutition was from this moment entirely impeded, and the contraction of the muscles expired to the most violent degree. A trachea, about as large as an egg, suddenly made its appearance both the lower and upper lip moved. After death, this was found to be caused by a rupture of one of the recti muscles, and a consequent extravasation of blood.—(*See also*, de Clair, *Med. v. 2, p. 277–289*.) This case is decidedly in support of the truth of the statement expressed on this subject by Hippocrates, Cullen, and Calaneo. The point is not so. It is mentioned by Sir James Macgillivray, that in the march of the guards through Gallipoli, one of them was attacked with tetanus, in consequence of a slight wound of the finger. As it was impossible to think of leaving the man in the retreat of the village where he was taken ill, he was carried on a blanket car, in the rear of the division. During the last part of the day he was stretched with pain, and there was standing at 32°; but, after ascending one of the highest mountains in Galicia, the patient was taken out of bed, and he was exposed from his in the morning to ten at night, when he was found half stricken to death, and five from every symptom of tetanus.—(*See* *Med. Clin. Trans.*, vol. 2, p. 430.)

Mr. Abernethy, in his lectures, expresses his conviction that in tetanus and all nervous affections, it is a most material point to operate on the brain, through the medium of the digestive organs, and that the production of narcotics from the alimentary canal has a more beneficial effect than any other means. He particularly commends the colligation of the stomach and jejunum, mixed with opium, as a means more than any other. Where much difficulty occurs in making the patient swallow, however, potestive medicine, it would strongly recommend to the administration of picrotoxin, the (doses light), a drop of which, blended with a little mucilage, and put on the root of the tongue, will operate powerfully on the bowels.

Another remedy still is here frequently effected a cure in tetanus is mercury.—(*See* *Ann. de Med.*, p. 45.) Mergatol frictions, practiced so as to induce a quick absorption of the agent, and in an early stage of the disorder, are justified. Others contend, that it matters not whether mercury be rubbed into the body or administered. It is positively asserted that opium may be advantageously exhibited at the same time. This practice was first adopted in the West India case. (*Edinb. Medical and Literary Essays*, vol. 3, p. 149.) It is recorded in many cases. Whatever benefit, however, may have been experienced from this plan is well known, it completely fails in the same form of the disease. Mergatol frictions appeared in Hæm. Læmy to aggravate the symptoms, in the cases where the skin was laid in Egypt. (*See* *de Clair*, *Med. v. 2, p. 277*); and Dr. Esmar, Mr. Guthrie, and other special officers attached to our army in the Peninsula, tried injections of the whole body, three times a day, with strong mercurial solution in oil administered, with no degree of success. After the battle of Trafalgar, a fatal case even occurred in a man, strongly affected by the influence of mercury, which he had been previously using for the cure of the itch.—(*See* *J. Macgillivray*, in *Med. Clin. Trans.*, vol. 5, p. 434.) The superiority of mercury, combined with picrotoxin, also proved its effectiveness in actual cases; but in chronic cases it proved abortive by keeping upon the bowels.

Another method of treating tetanus is that of administering the most powerful acids and stimulants, such as wine, brandy, ether, preparations of ammonia, bark, creosote, &c. The introduction of this plan was chiefly owing to the instance Dr. Rush, Professor of Medicine in Philadelphia, who published in the *Transactions of the American Philosophical Society*, vol. 2, a paper entitled "On the Cause and Cure of Tetanus." Dr. Rush considers tetanus as a disease essentially connected with debility, and he recommends for it the exhibition of the preceding class of remedies. He particularly advises the strong use of wine and Potassia lixiv; and as we have already stated, when tetanus comes from a wound, as directed the direction of it, and drops with oil of turpentine. Considerable success is mentioned as having attended the practice. Several other instances of success are also recorded by Dr. Huxham.—(*American Medical Repository*, vol. 2.)

Dr. Cullen, considering scorbutus, paralytic, apoplexy, chorea, and tetanus to be "affections of the nerves, or of those parts of the brain and spinal marrow which are immediately connected with them," was induced to try the effect of subcutaneous of iron (active examples of tetanic tetanus, in consequence of the success with which it had been exhibited in the other complaints above specified. Confinement to bed, with giving 5*ss*. of the iron, combined with, followed, when required, by the oil of olive. The quantity of this iron given in large fringed doses of 2*ss*, and given half an ounce, every two hours. It was mixed with wine in quantity of brandy, and blended with strong licorice. Two of the cases recovered; the third, which was one where the spasm was excessively violent, and the patient 148, was too rigid in its progress for an efficient trial of the remedy, the patient dying the day after the commencement of the plan.—(*See* *Med. Clin. Trans.*, vol. 15, p. 165, &c.) As tetanic tetanus has been occasionally cured under a variety of plans of treatment, it is difficult to draw any certain inference respecting the real utility of the exhibition of iron in that disorder, from the two examples of recovery published by Dr. Cullen.

Nothing is more certain proof of our not being acquainted with any very efficient method of treating a disease than a multiplicity of remedies which are as opposite in possible in their effects. We have seen that the contention Dr. Rush conceived, that tetanus was a disease connected with debility; and he has recorded examples in which it was successfully treated by acids and stimulants. Extraordinary, however, as it may appear, many practitioners are advocates for opium, especially in the early stage of tetanus. Dr. Dickson thinks that for a full trial, where the wound is healed, followed, and patient, sometimes, with free purging and such other topics as are calculated to allay the general and local irritation, affords the best chance of removing the danger.—(*See* *Med. Clin. Trans.*, vol. 2, part 3.) Harvey has also published several cases in which bleeding had a good effect. We are informed by Dr. James Macgillivray, that at our military hospitals in Spain sometimes had a few trials. In three cases at St. Andrea, decided by Dr. Galtier, this was the principal remedy. One patient with tetanus, from a wound of the back part of the hand, was died nearly of cholera several times with good effect, calomel and diaphoretic being also given, and he recovered. Another patient was laid in the same manner with such success, that he suffered but little from opium, and could open his mouth very well when he was mixed with doctored, which in his delirious state, caused him to do. In the third case, which was one of acute tetanus, symptoms, pointed to the throat, totally failed.—(*Opusc.*, vol. 2, p. 455–462.)

The powerful relaxing effects of tobacco chylers, in cases of tetanus and convulsions, have suggested a trial of them in tetanus. In one very acute case, the plan was tried by Mr. Keble, but it only afforded a temporary alleviation of the spasm, and so it called to more attention, it was discontinued. According to Sir James Macgillivray, tobacco chylers tried in the advanced stage of the disease seemed to have no effect. He considers, however, the tobacco fume as deserving to be tried.

A remarkable case is recorded by Dr. Phillips, in which the jaw suddenly fell upon the volubility of an acute attack of tetanus.—(*See* *Med. Clin. Trans.*, vol. 6, p. 50.)

by the side of the trachea, and even a little time afterwards this it. However, as these vessels proceed up the neck, they become more liberally supplied with respect to the trachea; and when they have arrived at the upper part of the neck, where persons who die at a death almost always die, they become situated more backwards than the trachea, including inside the angle of the lower jaw.

The esophagus is so deeply situated, lying close to the sides of the trachea, and behind the larynx, that it is not often concerned in any internal wounds, which do not immediately prove fatal, as consequence of the division of other important parts. Yet numerous cases are recorded in which the esophagus is said to have been wounded; and what is usually set down as a trifling accident, is the passage of victuals through the wound. In many of these instances, the writers seem to have forgotten that wounds made above the epipharynx, as they frequently lay very close to the neck, and the victuals escape through the cut, without the esophageal pharynx being in any danger.

However, as death the esophagus has occasionally been wounded, together with the trachea, not only without the patient perishing immediately so as to be incapable of receiving any support, but without every chance of recovery being destroyed. Scars and gunshot wounds may injure the esophagus, and leave all other important parts untouched. Nay, when other parts of the esophagus are injured, the patient is sometimes saved.—See *Hunter's Military Surgery*, p. 20, et. 2.

Even when the esophagus is known to be wounded, the deep situation would prohibit us from doing any thing to the breach of continuity in the tube itself. The best plan would be to have recourse to esophageal means, and to introduce a double canula catheter, from one of the wounds down the esophagus, for the purpose of conveying nourishment and medicines into the stomach, without any risk of their passing out at the wound. An instrument of this kind will be in the above situation for any length of time without producing much inconvenience, and besides being necessary for supplying nourishment and medicine down the passage, and keeping them from coming at the wound, it prevents all necessity for the wounded esophagus to set, and become disturbed, which more is seldom in any kind of lipids, especially in the way of nutrition or food. The outer wound should be brought together and treated on ordinary principles.

When persons cut their throats as I have explained, they do not often divide the carotid artery, owing to their incision being usually made high up in the neck, and this vessel has attained a very backward situation. When any serious hemorrhage does arise, it is sometimes from the lower branches of the thyroid artery, this most frequently from the superior thyroid artery. These arteries only causing a fatal bleeding, which, indeed, would more frequently be the event were it not so, it did not the patient often find, in such case the bleeding spontaneously ceases, and ceases for the arrival of surgical assistance.

I need hardly tell the reader that these vessels are to be tied, and that this important object is the first to which the surgeon should direct his attention. The chance of bleeding to death being obtained as soon as possible, the other surgical measures may be more deliberately executed.

With respect to wounds of the trachea, the prospects of conveying food and medicines into the stomach through an elastic tube, catheter, introduced from one of the wounds down the trachea is highly perilous, though too much neglected; for nothing tends so much to diminish of the natural action, as the inevitable division and exposure of the larynx and trachea, which are usually situated on the way of swallowing.

When the trachea is cut, the patient's power of forcing the air is more or less impaired, in consequence of the air passing into and out of the lungs chiefly through the wound. Besides this, a considerable quantity of the natural mucus of the trachea is also continually coming out of the wound.

The great means of accomplishing the union of wounds of the trachea, are a proper position of the head, and a supine situation of the patient. Bringing the patient's head with pillow, and keeping

his chin close to his breast, the edge of the wound ends inside skin and trachea, are placed in contact even without any other assistance, unless the diameter of the trachea be exceedingly large. It is proper, however, to procure the effect of a suitable position with strips of sticking plaster, and sometimes to fix a suture or two. But the severity for suture wound position on the extent of the diameter of the trachea; for almost most of the circle of this tube is cut, and position is neglected, the wound in it will not gape. The trachea should never be passed through the living of the trachea, as this method would be likely to make it adhere, and occasion considerable coughing and inflammation, attended with very pernicious effects.

Should there be great coughing, apparently arising from irritation and inflammation of the trachea, according to proper, if other considerations do not forbid it. The external trachea with often is also frequently of great service. It rarely acts a wound of the trachea made by the ligament.

[That wounds of the trachea do unite by the first intention would seem to be rendered probable, at least, by the easy recovery of patients after the operation of tracheotomy. This operation is now very frequently performed in this country, for the removal of foreign bodies from the trachea and sometimes for anastomosis or repair. Indeed I have known it inserted in difficulty in phthisis trachealis, but without benefit. The case however is sufficiently established, that the operation is seldom followed by any troublesome symptoms, and the trachea does unite in a very few days.]

In this operation it is true that the trachea is often perpendicular only, and the patient remains in such a way necessary, while in wounds of the throat as in attempted stitches, the trachea is generally wounded across its radius or between the rings. I sometimes seeing one of the trachea (which a man cut his throat with a razor, and divided the trachea entirely across and yet it united again by the treatment recommended by Mr. Cooper, and in a few weeks in voice and respiration had entirely recovered. We should always make the attempt, as he advised, and with very generally be successful.—*Doyle*]

See *John Hall on Wounds*, et. 3. *Hunter's Military Surgery*, p. 206, et. 2. *See* *Edin. 1820*. Among other references made by Dr. Hunter, the following may be of use to merit particular notice.—An interesting case of wound of the neck, attended by hemiplegia, and rupture of the trachea, is given by *Dr. Ferrius* in his *Surgical Observations*. Another with loss of motion in the arm, from a wound in the neck, is to be found in the *Edin. Med. Essays*, vol. 3. And in the *Med. Commentaries*, by Dr. Duguid, vol. 4, p. 634, and vol. 8, p. 256, are two interesting cases. *Montana*, in his *Med. Chir. Bibliotheca*, relates a case of removal of the thyroid gland by a common cut; the patient survived fourteen days, and died of hemorrhage. Wounds of the trachea often remain open for considerable periods, as is illustrated in a case reported by *Travers*, in his *Præsentation Observations*, Sept. 1745, p. 49. Mr. Ferrius has recorded an interesting case of wound of the trachea, in *Med. Chir. Journ.* vol. 1, p. 289. I would also refer to various parts of *Alm. de Chir. Milit.* by *Baron Larrey*; and *Thompson's Report of Chir. made in the Hospital de Edinburg*, *See* *Edin. 1820*.

THROMBOSIS. (*Edin. Solis*, coagulated blood.) A clot of blood. The term is also applied to a tumour, formed by a collection of extravasated coagulated blood, under the integuments after bleeding. When not considerable it is usually called an *æchymosis*—(see this word and *Ecchymosis*.)

A thrombus after bleeding generally arises from the opening in the vein not corresponding to that in the skin. The patient's throwing the position of the arm, before the blood is flowing into the vein, will often cause an obstruction in the escape of the blood from the external orifice of the pulsation; and consequently an increase itself into the cellular substance in the vicinity of the opening in the vein. In proportion as the blood issues from the vessel, it is effused in the cellular substance, between the skin and fibres, clashing the muscles; and this with more or less rapidity, and in a greater or less quantity, according to the colour of the skin more or less purple the outward cause of the thrombus. Sometimes, also, a thrombus forms

arteries, for the most part as large as the radial or digital, that is, in order to prevent further loss of blood, he directed us to tie the line at the swelling, and then cut away the ligament nearest the ligature. For this purpose he used a blunt-pointed mucousoidal needle, armed with two four-threaded ligatures. This was passed through the middle of the tumor, which the fingers were pulled upward, and was ligatured with three gradually tied over the tumor, and thereafter over the upper half of the tumor. For the sake of being still more sure of compressing the hemorrhage, M. Moreau also applied a third ligature all round the swelling, and he then re-estimated the dissected place, without any bleeding from the part incised at the ligature. These were now fastened at the sides of the wound with adhesive plaster. The whole surface of the wound was sprinkled with powdered pine resin, over which was laid again, wet with Tindal's vaseline ointment. These applications having been covered with stapes, the lips of the wound were drawn towards each other with adhesive plaster, which was also covered with ointment, wet with vaseline, and renewed every six or eight inches.
